• Describe the location, histology, hormones, and functions of the thyroid gland.

The butterfly-shaped thyroid gland is located just inferior to the larynx (voice box). It is composed of right and left lateral lobes, one on either side of the trachea, that are connected by an isthmus (IS-mus = a narrow passage) anterior to the trachea (Figure 18.10a). A small, pyramidal-shaped lobe sometimes extends upward from the isthmus. The normal mass of the thyroid is about 30 g (1 oz). It is highly vascularized and receives 80–120 mL of blood per minute.

Microscopic spherical sacs called thyroid follicles (Figure 18.10b) make up most of the thyroid gland. The wall of each follicle consists primarily of cells called follicular cells, most of which extend to the lumen (internal space) of the follicle. A basement membrane surrounds each follicle. When the follicular cells are inactive, their shape is low cuboidal to squamous, but under the influence of TSH they become active in secretion and range from cuboidal to low columnar in shape. The follicular cells produce two hormones: thyroxine (thi-ROK-sên), which is also called tetraiodothyronine (tet-ra-i'-o-dö-THI-rō-nēn) or T4 because it contains four atoms of iodine, and triiodothyronine (tri-i'-o-dö-THI-rō-nēn) or T3, which contains three atoms of iodine. T3 and T4 together are also known as thyroid hormones. A few cells called parafollicular cells or C cells lie between follicles. They produce the hormone calcitonin (kal-si-TÖ-nīn), which helps regulate calcium homeostasis.

Formation, Storage, and Release of Thyroid Hormones

The thyroid gland is the only endocrine gland that stores its secretory product in large quantities—normally about a 100-day supply. Synthesis and secretion of T3 and T4 occurs as follows (Figure 18.11 on page 660):
Figure 18.10 Location, blood supply, and histology of the thyroid gland.

Thyroid hormones regulate (1) oxygen use and basal metabolic rate, (2) cellular metabolism, and (3) growth and development.

Which cells secrete T₃ and T₄? Which secrete calcitonin? Which of these hormones are also called thyroid hormones?
Iodide trapping. Thyroid follicular cells trap iodide ions (I\(^{-}\)) by actively transporting them from the blood into the cytosol. As a result, the thyroid gland normally contains most of the iodide in the body.

Synthesis of thyroglobulin. While the follicular cells are trapping I\(^{-}\), they are also synthesizing thyroglobulin (TGB), a large glycoprotein that is produced in the rough endoplasmic reticulum, modified in the Golgi complex, and packaged into secretory vesicles. The vesicles then undergo exocytosis, which releases TGB into the lumen of the follicle.

Oxidation of iodide. Some of the amino acids in TGB are tyrosines that will become iodinated. However, negatively charged iodide ions cannot bind to tyrosine until they undergo oxidation (removal of electrons) to iodine: 2 I\(^{-}\) → I\(_2\). As the iodide ions are being oxidized, they pass through the membrane into the lumen of the follicle.

Iodination of tyrosine. As iodine molecules (I\(_2\)) form, they react with tyrosines that are part of thyroglobulin molecules. Binding of one iodine atom yields monoiodotyrosine (T\(_1\)), and a second iodination produces diiodotyrosine (T\(_2\)). The TGB with attached iodine atoms, a sticky material that accumulates and is stored in the lumen of the thyroid follicle, is termed colloid.

Coupling of T\(_1\) and T\(_2\). During the last step in the synthesis of thyroid hormone, two T\(_2\) molecules join to form T\(_4\) or one T\(_1\) and one T\(_2\) join to form T\(_3\).

Pinocytosis and digestion of colloid. Droplets of colloid reenter follicular cells by pinocytosis and merge with lysosomes. Digestive enzymes in the lysosomes break down TGB, cleaving off molecules of T\(_3\) and T\(_4\).

Secretion of thyroid hormones. Because T\(_3\) and T\(_4\) are lipid-soluble, they diffuse through the plasma membrane into interstitial fluid and then into the blood. T\(_4\) normally is secreted in greater quantity than T\(_3\), but T\(_3\) is several times more potent. Moreover, after T\(_2\) enters a body cell, most of it is converted to T\(_3\) by removal of one iodine.

Transport in the blood. More than 99% of both the T\(_3\) and the T\(_4\) combine with transport proteins in the blood, mainly thyroxine-binding globulin (TBG).

**Actions of Thyroid Hormones**

Because most body cells have receptors for thyroid hormones, T\(_3\) and T\(_4\) exert their effects throughout the body.

1. Thyroid hormones increase basal metabolic rate (BMR), the rate of oxygen consumption under standard or basal conditions (awake, at rest, and fasting), by stimulating the use of cellular oxygen to produce ATP. When the basal metabolic rate increases, cellular metabolism of carbohydrates, lipids, and proteins increases.

2. What is the storage form of thyroid hormones?
2. A second major effect of thyroid hormones is to stimulate synthesis of additional sodium-potassium pumps (Na\(^+/\)K\(^+\) ATPase), which use large amounts of ATP to continually eject sodium ions (Na\(^+\)) from the cytosol into the extracellular fluid and potassium ions (K\(^+\)) from the extracellular fluid into the cytosol. As cells produce and use more ATP, more heat is given off, and body temperature rises. This phenomenon is called the **calorigenic effect**. In this way, thyroid hormones play an important role in the maintenance of normal body temperature. Normal mammals can survive in freezing temperatures, but those whose thyroid glands have been removed cannot.

3. In the regulation of metabolism, the thyroid hormones stimulate protein synthesis and increase the use of glucose and fatty acids for ATP production. They also increase lipolysis and enhance cholesterol excretion, thus reducing body cholesterol level.

4. The thyroid hormones enhance some actions of the catecholamines (norepinephrine and epinephrine) because they up-regulate beta (β) receptors. For this reason, symptoms of hyperthyroidism include increased heart rate, more forceful heartbeats, and increased blood pressure.

5. Together with human growth hormone and insulin, thyroid hormones accelerate body growth, particularly the growth of the nervous and skeletal systems. Deficiency of thyroid hormones during fetal development, infancy, or childhood causes severe mental retardation and stunted bone growth.

### Control of Thyroid Hormone Secretion

Thyrotropin-releasing hormone (TRH) from the hypothalamus and thyroid-stimulating hormone (TSH) from the anterior pituitary stimulate synthesis and release of thyroid hormones, as shown in **Figure 18.12**:

1. Low blood levels of T\(_3\) and T\(_4\) or low metabolic rate stimulate the hypothalamus to secrete TRH.
2. TRH enters the hypophyseal portal veins and flows to the anterior pituitary, where it stimulates thyrotrophs to secrete TSH.
3. TSH stimulates virtually all aspects of thyroid follicular cell activity, including iodide trapping (**1** in **Figure 18.11**), hormone synthesis and secretion (**2** and **7** in **Figure 18.11**), and growth of the follicular cells.
4. The thyroid follicular cells release T\(_3\) and T\(_4\) into the blood until the metabolic rate returns to normal.
5. An elevated level of T\(_3\) inhibits release of TRH and TSH (negative feedback inhibition).

Conditions that increase ATP demand—a cold environment, hypoglycemia, high altitude, and pregnancy—also increase the secretion of the thyroid hormones.

### How could an iodine-deficient diet lead to goiter, which is an enlargement of the thyroid gland?

**Calcitonin**

The hormone produced by the parafollicular cells of the thyroid gland (see **Figure 18.10b**) is calcitonin (CT) (kal-si-TÔ-nin). CT can decrease the level of calcium in the blood by inhibiting the action of osteoclasts, the cells that break down bone extracellular matrix. The secretion of CT is controlled by a negative feedback system (see **Figure 18.14**).
When its blood level is high, calcitonin lowers the amount of blood calcium and phosphates by inhibiting bone resorption (breakdown of bone extracellular matrix) by osteoclasts and by accelerating uptake of calcium and phosphates into bone extracellular matrix. Miacalcin, a calcitonin extract derived from salmon that is 10 times more potent than human calcitonin, is prescribed to treat osteoporosis.

Table 18.6 summarizes the hormones produced by the thyroid gland, control of their secretion, and their principal actions.

**CHECKPOINT**

12. Explain how blood levels of T₃/T₄, TSH, and TRH would change in a laboratory animal that has undergone a thyroidectomy (complete removal of its thyroid gland).

13. How are the thyroid hormones synthesized, stored, and secreted?

14. How is the secretion of T₃ and T₄ regulated?

15. What are the physiological effects of the thyroid hormones?

**PARATHYROID GLANDS**

**OBJECTIVE**

- Describe the location, histology, hormone, and functions of the parathyroid glands.

Partially embedded in the posterior surface of the lateral lobes of the thyroid gland are several small, round masses of tissue called the parathyroid glands (para- = beside). Each has a mass of about 40 mg (0.04 g). Usually, one superior and one inferior parathyroid gland are attached to each lateral thyroid lobe (Figure 18.13a), for a total of four.

Microscopically, the parathyroid glands contain two kinds of epithelial cells (Figure 18.13b, c). The more numerous cells, called chief (principal) cells, produce parathyroid hormone (PTH), also called parathormone. The function of the other kind of cell, called an oxyphil cell, is not known.

**Parathyroid Hormone**

Parathyroid hormone is the major regulator of the levels of calcium (Ca²⁺), magnesium (Mg²⁺), and phosphate (HPO₄²⁻) ions in the blood. The specific action of PTH is to increase the number and activity of osteoclasts. The result is elevated bone resorption, which releases ionic calcium (Ca²⁺) and phosphates (HPO₄²⁻) into the blood. PTH also acts on the kidneys. First, it slows the rate at which Ca²⁺ and Mg²⁺ are lost from blood into the urine. Second, it increases loss of HPO₄²⁻ from blood into the urine. Because more HPO₄²⁻ is lost in the urine than is gained from the bones, PTH decreases blood HPO₄²⁻ level and increases blood Ca²⁺ and Mg²⁺ levels. A third effect of PTH on the kidneys is to promote formation of the hormone calcitriol, the active form of vitamin D. Calcitriol, also known as 1, 25-dihydroxy vitamin D₃, increases the rate of Ca²⁺, HPO₄²⁻, and Mg²⁺ absorption from the gastrointestinal tract into the blood.

The blood calcium level directly controls the secretion of both calcitonin and parathyroid hormone via negative feedback loops that do not involve the pituitary gland (Figure 18.14 on page 664):
Figure 18.13 Location, blood supply, and histology of the parathyroid glands.

The parathyroid glands, normally four in number, are embedded in the posterior surface of the thyroid gland.

What are the secretory products of (1) parafollicular cells of the thyroid gland and (2) chief (principal) cells of the parathyroid glands?
**CALCITRIOL** stimulates increased absorption of Ca\(^{2+}\) from foods, which increases blood Ca\(^{2+}\) level.

**PTH** also stimulates the kidneys to release **CALCITRIOL**.

**CALCITONIN** inhibits osteoclasts, thus decreasing blood Ca\(^{2+}\) level.

**PARATHYROID HORMONE (PTH)** promotes release of Ca\(^{2+}\) from bone extracellular matrix into blood and slows loss of Ca\(^{2+}\) in urine, thus increasing blood Ca\(^{2+}\) level.

**6** CALCITRIOL stimulates increased absorption of Ca\(^{2+}\) from foods, which increases blood Ca\(^{2+}\) level.

**5** PTH also stimulates the kidneys to release CALCITRIOL.

**3** Low level of Ca\(^{2+}\) in blood stimulates parathyroid gland chief cells to release more PTH.

**4** PARATHYROID HORMONE (PTH) promotes release of Ca\(^{2+}\) from bone extracellular matrix into blood and slows loss of Ca\(^{2+}\) in urine, thus increasing blood Ca\(^{2+}\) level.

**2** CALCITONIN inhibits osteoclasts, thus decreasing blood Ca\(^{2+}\) level.

**6** CALCITRIOL stimulates increased absorption of Ca\(^{2+}\) from foods, which helps increase the blood level of Ca\(^{2+}\).

**What are the primary target tissues for PTH, CT, and calcitriol?**

1. A higher-than-normal level of calcium ions (Ca\(^{2+}\)) in the blood stimulates parafollicular cells of the thyroid gland to release more calcitonin.
2. Calcitonin inhibits the activity of osteoclasts, thereby decreasing the blood Ca\(^{2+}\) level.
3. A lower-than-normal level of Ca\(^{2+}\) in the blood stimulates chief cells of the parathyroid gland to release more PTH.
4. PTH promotes resorption of bone extracellular matrix, which releases Ca\(^{2+}\) into the blood and slows loss of Ca\(^{2+}\) in the urine, raising the blood level of Ca\(^{2+}\).
5. PTH also stimulates the kidneys to synthesize calcitriol, the active form of vitamin D.
6. Calcitriol stimulates increased absorption of Ca\(^{2+}\) from foods in the gastrointestinal tract, which helps increase the blood level of Ca\(^{2+}\).

16. How is secretion of parathyroid hormone regulated?

17. In what ways are the actions of PTH and calcitriol similar? How are they different?

**ADRENAL GLANDS**

**OBJECTIVE**
- Describe the location, histology, hormones, and functions of the adrenal glands.

The paired adrenal (suprarenal) glands, one of which lies superior to each kidney in the retroperitoneal space (Figure 18.15a), have a flattened pyramidal shape. In an adult, each adrenal gland is 3–5 cm in height, 2–3 cm in width, and a little less than 1 cm thick, with a mass of 3.5–5 g, only half its size at birth. During embryonic development, the adrenal glands differentiate into two structurally and functionally distinct regions: a large, peripherally located adrenal cortex, comprising 80–90% of the gland, and a small, centrally located adrenal medulla (Figure 18.15b). A connective tissue capsule covers the gland. The adrenal glands, like the thyroid gland, are highly vascularized.

The adrenal cortex produces steroid hormones that are essential for life. Complete loss of adrenocortical hormones leads to death due to dehydration and electrolyte imbalances in a few days to a week, unless hormone replacement therapy begins promptly. The adrenal medulla produces three catecholamine hormones—norepinephrine, epinephrine, and a small amount of dopamine.

**Adrenal Cortex**

The adrenal cortex is subdivided into three zones, each of which secretes different hormones (Figure 18.15d). The outer zone, just deep to the connective tissue capsule, is the zona glomerulosa (zona = belt; glomerul- = little ball). Its cells, which are closely packed and arranged in spherical clusters and arched columns, secrete hormones called mineralocorticoids (min’-er-al-o¯-KOR-ti-koyds) because they affect mineral homeostasis. The middle zone, or zona fasciculata (fascicul- = little bundle), is the widest of the three zones and consists of cells arranged in long, straight columns. The cells of the zona fascicu-
lata secrete mainly glucocorticoids (gloo-kō-KOR-ti-koyds), so named because they affect glucose homeostasis. The cells of the inner zone, the zona reticularis (reticul- = network), are arranged in branching cords. They synthesize small amounts of weak androgens (andro- = a man), steroid hormones that have masculinizing effects.

**Mineralocorticoids**

Aldosterone (al-DOS-ter-ôn) is the major mineralocorticoid. It regulates homeostasis of two mineral ions, namely sodium ions (Na⁺) and potassium ions (K⁺), and helps adjust blood pressure and blood volume. Aldosterone also promotes excretion of H⁺ in the urine; this removal of acids from the body can help prevent acidosis (blood pH below 7.35), which is discussed in Chapter 27.

The renin–angiotensin–aldosterone or RAA pathway (RÉ-nin an’-jē-ô-TEN-sin) controls secretion of aldosterone (Figure 18.16):

1. Stimuli that initiate the renin–angiotensin–aldosterone pathway include dehydration, Na⁺ deficiency, or hemorrhage.
2. These conditions cause a decrease in blood volume.
3. Decreased blood volume leads to decreased blood pressure.
4. Lowered blood pressure stimulates certain cells of the kidneys, called juxtaglomerular cells, to secrete the enzyme renin.
5. The level of renin in the blood increases.
6. Renin converts angiotensinogen, a plasma protein produced by the liver, into angiotensin I.
7. Blood containing increased levels of angiotensin I circulates in the body.
8. As blood flows through capillaries, particularly those of the lungs, the enzyme angiotensin-converting enzyme (ACE) converts angiotensin I into the hormone angiotensin II.
10. Angiotensin II stimulates the adrenal cortex to secrete aldosterone.
11. Blood containing increased levels of aldosterone circulates to the kidneys.
12. In the kidneys, aldosterone increases reabsorption of Na⁺ and water so that less is lost in the urine. Aldosterone also stimulates the kidneys to increase secretion of K⁺ and H⁺ into the urine.
13. With increased water reabsorption by the kidneys, blood volume increases.
As blood volume increases, blood pressure increases to normal.

Angiotensin II also stimulates contraction of smooth muscle in the walls of arterioles. The resulting vasoconstriction of the arterioles increases blood pressure and thus helps raise blood pressure to normal.

Besides angiotensin II, a second stimulator of aldosterone secretion is an increase in the $K^+/H^+$ concentration of blood (or interstitial fluid). A decrease in the blood $K^+$ level has the opposite effect.

Glucocorticoids

The glucocorticoids, which regulate metabolism and resistance to stress, include cortisol (hydrocortisone), corticosterone, and cortisone. Of these three hormones secreted by the zona fasciculata, cortisol is the most abundant, accounting for about 95% of glucocorticoid activity.

Control of glucocorticoid secretion occurs via a typical negative feedback system (Figure 18.17). Low blood levels of glucocorticoids, mainly cortisol, stimulate neurosecretory cells in the hypothalamus to secrete corticotropin-releasing hormone (CRH). CRH (together with a low level of cortisol) promotes the release of ACTH from the anterior pituitary. ACTH flows in the blood to the adrenal cortex, where it stimulates glucocorticoid secretion. (To a much smaller extent, ACTH also stimulates secretion of aldosterone.) The discussion of stress at the end of the chapter describes how the hypothalamus also increases CRH release in response to a variety of physical and emotional stresses.

Glucocorticoids have the following effects:

1. **Protein breakdown.** Glucocorticoids increase the rate of protein breakdown, mainly in muscle fibers, and thus increase the liberation of amino acids into the bloodstream. The amino acids may be used by body cells for synthesis of new proteins or for ATP production.

2. **Glucose formation.** Upon stimulation by glucocorticoids, liver cells may convert certain amino acids or lactic acid to glucose, which neurons and other cells can use for ATP production. Such conversion of a substance other than glycogen or another monosaccharide into glucose is called **gluconeogenesis** (gloo'-ko-ne' -ə-JEN-e-sis).

3. **Lipolysis.** Glucocorticoids stimulate **lipolysis**, the breakdown of triglycerides and release of fatty acids from adipose tissue into the blood.
4. **Resistance to stress.** Glucocorticoids work in many ways to provide resistance to stress. The additional glucose supplied by the liver cells provides tissues with a ready source of ATP to combat a range of stresses, including exercise, fasting, fright, temperature extremes, high altitude, bleeding, infection, surgery, trauma, and disease. Because glucocorticoids make blood vessels more sensitive to other hormones that cause vasoconstriction, they raise blood pressure. This effect would be an advantage in cases of severe blood loss, which causes blood pressure to drop.

5. **Anti-inflammatory effects.** Glucocorticoids inhibit white blood cells that participate in inflammatory responses. Unfortunately, glucocorticoids also retard tissue repair, and as a result, they slow wound healing. Although high doses can cause severe mental disturbances, glucocorticoids are very useful in the treatment of chronic inflammatory disorders such as rheumatoid arthritis.

6. **Depression of immune responses.** High doses of glucocorticoids depress immune responses. For this reason, glucocorticoids are prescribed for organ transplant recipients to retard tissue rejection by the immune system.

---

**Androgens**

In both males and females, the adrenal cortex secretes small amounts of weak androgens. The major androgen secreted by the adrenal gland is dehydroepiandrosterone (DHEA) (\(\text{dē-hi-drō-ep'-ē-an-DROS-ter-o¯n}\)). After puberty in males, the androgen testosterone is also released in much greater quantity by the testes. Thus, the amount of androgens secreted by the adrenal gland in males is usually so low that their effects are insignificant. In females, however, adrenal androgens play important roles. They promote libido (sex drive) and are converted into estrogens (feminizing sex steroids) by other body tissues. After menopause, when ovarian secretion of estrogens ceases, all female estrogens come from conversion of adrenal androgens. Adrenal androgens also stimulate growth of axillary and pubic hair in boys and girls and contribute to the prepubertal growth spurt. Although control of adrenal androgen secretion is not fully understood, the main hormone that stimulates its secretion is ACTH.

---

**Clinical Connection: Congenital Adrenal Hyperplasia**

Congenital adrenal hyperplasia (CAH) is a genetic disorder in which one or more enzymes needed for synthesis of cortisol are absent. Because the cortisol level is low, secretion of ACTH by the anterior pituitary is high due to lack of negative feedback inhibition. ACTH in turn stimulates growth and secretory activity of the adrenal cortex. As a result, both adrenal glands are enlarged. However, certain steps leading to synthesis of cortisol are blocked. Thus, precursor molecules accumulate, and some of these are weak androgens that can undergo conversion to testosterone. The result is virilism, or masculinization. In a female, virile characteristics include growth of a beard, development of a much deeper voice and a masculine distribution of body hair, growth of the clitoris so it may resemble a penis, atrophy of the breasts, and increased muscularity that produces a masculine physique. In prepubertal males, the syndrome causes the same characteristics as in females, plus rapid development of the male sexual organs and emergence of male sexual desires. In adult males, the virilizing effects of CAH are usually completely obscured by the normal virilizing effects of the testosterone secreted by the testes. As a result, CAH is often diffi-
Adrenal Medulla

The inner region of the adrenal gland, the adrenal medulla, is a modified sympathetic ganglion of the autonomic nervous system (ANS). It develops from the same embryonic tissue as all other sympathetic ganglia, but its cells, which lack axons, form clusters around large blood vessels. Rather than releasing a neurotransmitter, the cells of the adrenal medulla secrete hormones. The hormone-producing cells, called chromaffin cells (KRÖ-maf-in; chrom- = color; -affin = affinity for; see Figure 18.15d), are innervated by sympathetic preganglionic neurons of the ANS. Because the ANS exerts direct control over the chromaffin cells, hormone release can occur very quickly.

The two major hormones synthesized by the adrenal medulla are epinephrine and norepinephrine (NE), also called adrenaline and noradrenaline, respectively. The chromaffin cells of the adrenal medulla secrete an unequal amount of these hormones—about 80% epinephrine and 20% norepinephrine. Unlike the hormones of the adrenal cortex, the hormones of the adrenal medulla are not essential for life since they only intensify sympathetic responses in other parts of the body.

In stressful situations and during exercise, impulses from the hypothalamus stimulate sympathetic preganglionic neurons, which in turn stimulate the chromaffin cells to secrete epinephrine and norepinephrine. These two hormones greatly augment the fight-or-flight response that you learned about in Chapter 15. By increasing heart rate and force of contraction, epinephrine and norepinephrine increase the output of the heart, which increases blood pressure. They also increase blood flow to the heart, liver, skeletal muscles, and adipose tissue; dilate airways to the lungs; and increase blood levels of glucose and fatty acids.

Table 18.8 summarizes the hormones produced by the adrenal glands, control of their secretion, and their principal actions.

CHECKPOINT
18. How do the adrenal cortex and adrenal medulla compare with regard to location and histology?
19. How is secretion of adrenal cortex hormones regulated?
20. How is the adrenal medulla related to the autonomic nervous system?

PANCREATIC ISLETS

OBJECTIVE
• Describe the location, histology, hormones, and functions of the pancreatic islets.

The pancreas (pan- = all; -creas = flesh) is both an endocrine gland and an exocrine gland. We discuss its endocrine functions here and include its exocrine functions in Chapter 24 in the

Adrenal cortex

Andrenal medulla
Is the pancreas an exocrine gland or an endocrine gland?
coverage of the digestive system. A flattened organ that measures about 12.5–15 cm (4.5–6 in.) in length, the pancreas is located in the curve of the duodenum, the first part of the small intestine, and consists of a head, a body, and a tail (Figure 18.18a). Roughly 99% of the cells of the pancreas are arranged in clusters called acini. The acini produce digestive enzymes, which flow into the gastrointestinal tract through a network of ducts. Scattered among the exocrine acini are 1–2 million tiny clusters of endocrine tissue called pancreatic islets or islets of Langerhans (LAHNG-er-hanz; Figure 18.18b, c). Abundant capillaries serve both the exocrine and endocrine portions of the pancreas.

Cell Types in the Pancreatic Islets

Each pancreatic islet includes four types of hormone-secreting cells:

1. **Alpha or A cells** constitute about 17% of pancreatic islet cells and secrete glucagon (GLOO-ka-gon).
2. **Beta or B cells** constitute about 70% of pancreatic islet cells and secrete insulin (IN-soo-lin).
3. **Delta or D cells** constitute about 7% of pancreatic islet cells and secrete somatostatin (identical to the growth hormone–inhibiting hormone secreted by the hypothalamus).
4. **F cells** constitute the remainder of pancreatic islet cells and secrete pancreatic polypeptide.

The interactions of the four pancreatic hormones are complex and not completely understood. We do know that glucagon raises blood glucose level, and insulin lowers it. Somatostatin acts in a paracrine manner to inhibit both insulin and glucagon release from neighboring beta and alpha cells. It may also act as a circulating hormone to slow absorption of nutrients from the gastrointestinal tract. Pancreatic polypeptide inhibits somatostatin secretion, gallbladder contraction, and secretion of digestive enzymes by the pancreas.

Regulation of Glucagon and Insulin Secretion

The principal action of glucagon is to increase blood glucose level when it falls below normal. Insulin, on the other hand, helps lower blood glucose level when it is too high. The level of blood glucose controls secretion of glucagon and insulin via negative feedback (Figure 18.19):

1. Low blood glucose (hypoglycemia) stimulates secretion of glucagon from alpha cells of the pancreatic islets.
2. Glucagon acts on hepatocytes (liver cells) to accelerate the conversion of glycogen into glucose (glycogenolysis) and to promote formation of glucose from lactic acid and certain amino acids (gluconeogenesis).
3. As a result, hepatocytes release glucose into the blood more rapidly, and blood glucose level rises.
4. If blood glucose continues to rise, high blood glucose level (hyperglycemia) inhibits release of glucagon (negative feedback).
5. High blood glucose (hyperglycemia) stimulates secretion of insulin by beta cells of the pancreatic islets.
6. Insulin acts on various cells in the body to accelerate facilitated diffusion of glucose into cells; to speed conversion of glucose into glycogen (glycogenesis); to increase uptake of amino acids by cells and to increase protein synthesis; to speed synthesis of fatty acids (lipogenesis); to slow the conversion of glycogen to glucose (glycogenolysis); and to slow the formation of glucose from lactic acid and amino acids (gluconeogenesis).
7. As a result, blood glucose level falls.
8. If blood glucose level drops below normal, low blood glucose inhibits release of insulin (negative feedback) and stimulates release of glucagon.

Figure 18.19 Negative feedback regulation of the secretion of glucagon (blue arrows) and insulin (orange arrows).

- Low blood glucose stimulates release of glucagon; high blood glucose stimulates secretion of insulin.
- Glucagon acts on hepatocytes (liver cells) to:
  - convert glycogen into glucose (glycogenolysis)
  - form glucose from lactic acid and certain amino acids (gluconeogenesis)
- Glucose released by hepatocytes raises blood glucose level to normal.
- If blood glucose continues to rise, hyperglycemia inhibits release of glucagon.
- Insulin acts on various body cells to:
  - accelerate facilitated diffusion of glucose into cells
  - speed conversion of glucose into glycogen (glycogenesis)
  - increase uptake of amino acids and increase protein synthesis
  - speed synthesis of fatty acids (lipogenesis)
  - slow glycogenolysis
  - slow gluconeogenesis
- Blood glucose level falls
- If blood glucose continues to fall, hypoglycemia inhibits release of insulin
- Does glucogenolysis increase or decrease blood glucose level?
Although blood glucose level is the most important regulator of insulin and glucagon, several hormones and neurotransmitters also regulate the release of these two hormones. In addition to the responses to blood glucose level just described, glucagon stimulates insulin release directly; insulin has the opposite effect, suppressing glucagon secretion. As blood glucose level declines and less insulin is secreted, the alpha cells of the pancreas are released from the inhibitory effect of insulin so they can secrete more glucagon. Indirectly, human growth hormone (hGH) and adrenocorticotropic hormone (ACTH) stimulate secretion of insulin because they act to elevate blood glucose.

Insulin secretion is also stimulated by:

- Acetylcholine, the neurotransmitter liberated from axon terminals of parasympathetic vagus nerve fibers that innervate the pancreatic islets
- The amino acids arginine and leucine, which would be present in the blood at higher levels after a protein-containing meal
- Glucose-dependent insulinotropic peptide (GIP),* a hormone released by enteroendocrine cells of the small intestine in response to the presence of glucose in the gastrointestinal tract

Although blood glucose level is the most important regulator of insulin and glucagon, several hormones and neurotransmitters also regulate the release of these two hormones. In addition to the responses to blood glucose level just described, glucagon stimulates insulin release directly; insulin has the opposite effect, suppressing glucagon secretion. As blood glucose level declines and less insulin is secreted, the alpha cells of the pancreas are released from the inhibitory effect of insulin so they can secrete more glucagon. Indirectly, human growth hormone (hGH) and adrenocorticotropic hormone (ACTH) stimulate secretion of insulin because they act to elevate blood glucose.

Insulin secretion is also stimulated by:

- Acetylcholine, the neurotransmitter liberated from axon terminals of parasympathetic vagus nerve fibers that innervate the pancreatic islets
- The amino acids arginine and leucine, which would be present in the blood at higher levels after a protein-containing meal
- Glucose-dependent insulinotropic peptide (GIP),* a hormone released by enteroendocrine cells of the small intestine in response to the presence of glucose in the gastrointestinal tract

*GIP—previously called gastric inhibitory peptide—was renamed because at physiological concentration its inhibitory effect on stomach function is negligible.

Thus, digestion and absorption of food containing both carbohydrates and proteins provide strong stimulation for insulin release.

Glucagon secretion is stimulated by:

- Increased activity of the sympathetic division of the ANS, as occurs during exercise
- A rise in blood amino acids if blood glucose level is low, which could occur after a meal that contained mainly protein

Table 18.9 on page 672 summarizes the hormones produced by the pancreas, control of their secretion, and their principal actions.

**CHECKPOINT**

21. How are blood levels of glucagon and insulin controlled?
22. What are the effects on secretion of insulin and glucagon of exercise versus eating a carbohydrate- and protein-rich meal?

### OVARIIES AND TESTES

**OBJECTIVE**

- Describe the location, hormones, and functions of the male and female gonads.

**Gonads** are the organs that produce gametes—sperm in males and oocytes in females. In addition to their reproductive function, the gonads secrete hormones. The **ovaries**, paired oval bodies located in the female pelvic cavity, produce several steroid hormones including two estrogens (estradiol and estrone) and progesterone. These female sex hormones, along with FSH and LH from the anterior pituitary, regulate the menstrual cycle, maintain pregnancy, and prepare the mammary glands for lactation. They also promote enlargement of the breasts and widening of the hips at puberty, and help maintain these female secondary sex characteristics. The ovaries also produce inhibin, a protein hormone that inhibits secretion of follicle-stimulating hormone (FSH). During pregnancy, the ovaries and placenta produce a peptide hormone called relaxin, which increases the flexibility of the pubic symphysis during pregnancy and helps dilate the uterine cervix during labor and delivery. These actions help ease the baby’s passage by enlarging the birth canal.

The male gonads, the **testes**, are oval glands that lie in the scrotum. The main hormone produced and secreted by the testes is testosterone, an androgen or male sex hormone. Testosterone stimulates descent of the testes before birth, regulates spermatogenesis, and promotes development and maintenance of male secondary sex characteristics, such as beard growth and deepening of the voice. The testes also produce inhibin, which inhibits secretion of FSH. The detailed structure of the ovaries and testes and the specific roles of sex hormones are discussed in Chapter 28.

Table 18.10 summarizes the hormones produced by the ovaries and testes and their principal actions.

**CHECKPOINT**

23. Why are the ovaries and testes classified as endocrine glands as well as reproductive organs?

### PINEAL GLAND

**OBJECTIVE**

- Describe the location, histology, hormone, and functions of the pineal gland.

The **pineal gland** (PIN-é-al = pinecone shape) is a small endocrine gland attached to the roof of the third ventricle of the brain at the midline (see Figure 18.1). Part of the epithalamus, it is positioned between the two superior colliculi, has a mass of 0.1–0.2 g, and is covered by a capsule formed by the pia mater. The gland consists of masses of neuroglia and secretory cells called pinealocytes (pin-é-AL-ō-sitz).

The pineal gland secretes melatonin, an amine hormone derived from serotonin. Melatonin appears to contribute to the setting of the body’s biological clock, which is controlled by the suprachiasmatic nucleus of the hypothalamus. As more melatonin is liberated during darkness than in light, this hormone is thought to promote sleepiness. In response to visual input from the eyes (retina), the suprachiasmatic nucleus stimulates sympathetic postganglionic neurons of the superior cervical ganglion, which in turn stimulate the pinealocytes of the pineal gland to secrete melatonin in a rhythmic pattern, with low levels of melatonin secreted during
the day and significantly higher levels secreted at night. During sleep, plasma levels of melatonin increase tenfold and then decline to a low level again before awakening. Small doses of melatonin given orally can induce sleep and reset daily rhythms, which might benefit workers whose shifts alternate between daylight and nighttime hours. Melatonin also is a potent antioxidant that may provide some protection against damaging oxygen free radicals.

In animals that breed during specific seasons, melatonin inhibits reproductive functions, but it is unclear whether melatonin influences human reproductive function. Melatonin levels are higher in children and decline with age into adulthood, but there is no evidence that changes in melatonin secretion correlate with the onset of puberty and sexual maturation. Nevertheless, because melatonin causes atrophy of the gonads in several animal species, the possibility of adverse effects on human reproduction must be studied before its use to reset daily rhythms can be recommended.

**Hormones from Other Endocrine Tissues and Organs**

As you learned at the beginning of this chapter, cells in organs other than those usually classified as endocrine glands have an endocrine function and secrete hormones. You learned about several of these in this chapter: the hypothalamus, thymus, pancreas, ovaries, and testes. Table 18.11 provides an overview of these organs and tissues and their hormones and actions.

Eicosanoids

Two families of eicosanoid molecules—the prostaglandins (pros’ta-GLAN-dins), or PGs, and the leukotrienes (loo-kö-TRI-ëns), or LTs—are found in virtually all body cells except red blood cells, where they act as local hormones (paracrines or autocrines) in response to chemical or mechanical stimuli. They are synthesized by clipping a 20-carbon fatty acid called arachidonic acid from membrane phospholipid molecules. From arachidonic acid, different enzymatic reactions produce PGs or LTs. Thromboxane (TX) is a modified PG that constricts blood vessels and promotes platelet activation. Appearing in the blood in minute quantities, eicosanoids are present only briefly due to rapid inactivation.

To exert their effects, eicosanoids bind to receptors on target-cell plasma membranes and stimulate or inhibit the synthesis of second messengers such as cyclic AMP. Leukotrienes stimulate chemotaxis (attraction to a chemical stimulus) of white blood cells and mediate inflammation. The prostaglandins alter smooth muscle contraction, glandular secretions, blood flow, reproductive processes, platelet function, respiration, nerve impulse transmission, lipid metabolism, and immune responses. They also have roles in promoting inflammation and fever, and in intensifying pain.

Growth Factors

Several of the hormones we have described—insulin-like growth factor, thyrosin, insulin, thyroid hormones, human growth hormone, and prolactin—stimulate cell growth and division. In addition, several more recently discovered hormones called growth factors play important roles in tissue development, growth, and repair. Growth factors are mitogenic substances—they cause growth by stimulating cell division. Many growth factors act locally, as autocrines or paracrines.

A summary of sources and actions of six important growth factors is presented in Table 18.12.

CHECKPOINT

25. What hormones are secreted by the gastrointestinal tract, placenta, kidneys, skin, adipose tissue, and heart?
26. What are some functions of prostaglandins, leukotrienes, and growth factors?

THE STRESS RESPONSE

OBJECTIVE

• Describe how the body responds to stress.

It is impossible to remove all of the stress from our everyday lives. Some stress, called eustress, prepares us to meet certain challenges and thus is helpful. Other stress, called distress, is harmful. Any stimulus that produces a stress response is called a stressor. A stressor may be almost any disturbance of the human body—heat or cold, environmental poisons, toxins given off by bacteria, heavy bleeding from a wound or surgery, or a strong emotional reaction. The responses to stressors may be pleasant or unpleasant, and they vary among people and even within the same person at different times.
Your body’s homeostatic mechanisms attempt to counteract stress. When they are successful, the internal environment remains within normal physiological limits. If stress is extreme, unusual, or long lasting, the normal mechanisms may not be enough. In 1936, Hans Selye, a pioneer in stress research, showed that a variety of stressful conditions or noxious agents elicit a similar sequence of bodily changes. These changes, called the stress response or general adaptation syndrome (GAS), are controlled mainly by the hypothalamus. The stress response occurs in three stages: (1) an initial fight-or-flight response, (2) a slower resistance reaction, and eventually (3) exhaustion.

The Fight-or-Flight Response

The fight-or-flight response, initiated by nerve impulses from the hypothalamus to the sympathetic division of the autonomic nervous system (ANS), including the adrenal medulla, quickly mobilizes the body’s resources for immediate physical activity (Figure 18.20a). It brings huge amounts of glucose and oxygen to the organs that are most active in warding off danger: the brain, which must become highly alert; the skeletal muscles, which may have to fight off an attacker or flee; and the heart, which must work vigorously to pump enough blood to the brain and muscles. During the fight-or-flight response, nonessential body functions such as digestive, urinary, and reproductive activities are inhibited. Reduction of blood flow to the kidneys promotes release of renin, which sets into motion the renin–angiotensin–aldosterone pathway (see Figure 18.16). Aldosterone causes the kidneys to retain Na⁺, which leads to water retention and elevated blood pressure. Water retention also helps preserve body fluid volume in the case of severe bleeding.

The Resistance Reaction

The second stage in the stress response is the resistance reaction (Figure 18.20b). Unlike the short-lived fight-or-flight response, which is initiated by nerve impulses from the hypothalamus, the resistance reaction is initiated in large part by hypothalamic releasing hormones and is a longer-lasting response. The hormones involved are corticotropin-releasing hormone (CRH), growth hormone–releasing hormone (GHRH), and thyrotropin-releasing hormone (TRH).

CRH stimulates the anterior pituitary to secrete ACTH, which in turn stimulates the adrenal cortex to increase release of cortisol. Cortisol then stimulates glucocorticogenesis by liver cells, breakdown of triglycerides into fatty acids (lipolysis), and catalysis of proteins into amino acids. Tissues throughout the body can use the resulting glucose, fatty acids, and amino acids to produce ATP or to repair damaged cells. Cortisol also reduces inflammation.

A second hypothalamic releasing hormone, GHRH, causes the anterior pituitary to secrete human growth hormone (hGH). Acting via insulinlike growth factors, hGH stimulates lipolysis and glycogenolysis, the breakdown of glycogen to glucose, in the liver. A third hypothalamic releasing hormone, TRH, stimulates the anterior pituitary to secrete thyroid-stimulating hormone (TSH). TSH promotes secretion of thyroid hormones, which stimulate the increased use of glucose for ATP production. The combined actions of hGH and TSH supply additional ATP for metabolically active cells throughout the body.

The resistance stage helps the body continue fighting a stressor long after the fight-or-flight response dissipates. This is why your heart continues to pound for several minutes even after the stressor is removed. Generally, it is successful in seeing us through a stressful episode, and our bodies then return to normal. Occasionally, however, the resistance stage fails to combat the stressor, and the body moves into the state of exhaustion.

Exhaustion

The resources of the body may eventually become so depleted that they cannot sustain the resistance stage, and exhaustion ensues. Prolonged exposure to high levels of cortisol and other hormones involved in the resistance reaction causes wasting of muscle, suppression of the immune system, ulceration of the gastrointestinal tract, and failure of pancreatic beta cells. In addition, pathological changes may occur because resistance reactions persist after the stressor has been removed.

Stress and Disease

Although the exact role of stress in human diseases is not known, it is clear that stress can lead to particular diseases by temporarily inhibiting certain components of the immune system. Stress-related disorders include gastritis, ulcerative colitis, irritable bowel syndrome, hypertension, asthma, rheumatoid arthritis (RA), migraine headaches, anxiety, and depression. People under stress are at a greater risk of developing chronic disease or dying prematurely.

Interleukin-1, a substance secreted by macrophages of the immune system (see page 655), is an important link between stress and immunity. One action of interleukin-1 is to stimulate secretion of ACTH, which in turn stimulates the production of cortisol. Not only does cortisol provide resistance to stress and inflammation, but it also suppresses further production of interleukin-1. Thus, the immune system turns on the stress response, and the resulting cortisol then turns off one immune system mediator. This negative feedback system keeps the immune response in check once it has accomplished its goal. Because of this activity, cortisol and other glucocorticoids are used as immunosuppressive drugs for organ transplant recipients.

---

**CLINICAL CONNECTION** Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is an anxiety disorder that may develop in an individual who has experienced, witnessed, or learned about a physically or psychologically distressing event. The immediate cause of PTSD appears to be the specific stressors associated with the events. Among the stressors are terrorism, hostage taking, imprisonment, military duty, serious accidents, torture, sexual or physical abuse,
Figure 18.20  Responses to stressors during the stress response. Red arrows (hormonal responses) and green arrows (neural responses) in (a) indicate immediate “fight-or-flight” reactions; black arrows in (b) indicate long-term resistance reactions.

Stressors stimulate the hypothalamus to initiate the stress response through the fight-or-flight response and the resistance reaction.

**Key:**
- CRH = Corticotropin-releasing hormone
- ACTH = Adrenocorticotropic hormone
- GHRH = Growth hormone-releasing hormone
- hGH = Human growth hormone
- TRH = Thyrotropin-releasing hormone
- TSH = Thyroid-stimulating hormone

---

**Stress Responses**
- Increased use of glucose to produce ATP
- Lipolysis
- Gluconeogenesis
- Protein catabolism
- Sensitized blood vessels
- Reduced inflammation

**(a) “Fight-or-flight” responses**
- Increased heart rate and force of beat
- Constriction of blood vessels of most viscera and skin
- Dilation of blood vessels of heart, lungs, brain, and skeletal muscles
- Contraction of spleen
- Conversion of glycogen into glucose in liver
- Sweating
- Dilation of airways
- Decrease in digestive activities
- Water retention and elevated blood pressure

**Stress Responses**
- Increased use of glucose to produce ATP

**Stress Responses**
- Lipolysis
- Glycogenolysis

**Stress Responses**
- Adrenal medulla
- Sympathetic centers in spinal cord
- Nerve impulses
- Sympathetic nerves
- Visceral effectors
- Adrenal cortex
- Liver
- Thyroid gland
- Thyroid hormones (T3 and T4)
- IGFs
- Cortisol

---

What is the basic difference between the stress response and homeostasis?
visceral cells that migrate to the superior pole of the kidney. Recall that adrenal medulla secrete steroid hormones all are derived from mesoderm. The that produces the gonads. Endocrine tissues that mesoderm that arise during the fifth week and have completely different embryological ori-

tves from the floor of the pharynx at the level of the second pair of pharyngeal pouches. The pouch grows toward the roof of the mouth. The pouch grows toward the roof of the mouth called the hypophyseal (Rathke’s) pouch. The pouch grows toward the roof of the mouth.

The thyroid gland develops during the fourth week as an outgrowth of endoderm from the floor of the hypothalamus (Figure 18.21). The infundibulum, also an outgrowth of the neurohypophyseal bud, connects the posterior pituitary to the hypothalamus. The anterior pituitary (adenohypophysis) is derived from an outgrowth of endoderm from the roof of the mouth called the hypophyseal (Rathke’s) pouch. The pouch grows toward the neurohypophyseal bud and eventually loses its connection with the roof of the mouth.

The thyroid gland develops during the fourth week as a mid-ventral outgrowth of endoderm, called the thyroid diverticulum, from the floor of the pharynx at the level of the second pair of pharyngeal pouches (Figure 18.21a). The outgrowth projects inferiorly and differentiates into the right and left lateral lobes and the isthmus of the gland.

The parathyroid glands develop during the fourth week from endoderm as outgrowths from the third and fourth pharyngeal pouches, which help to form structures of the head and neck.

The adrenal cortex and adrenal medulla develop during the fifth week and have completely different embryological origins. The adrenal cortex is derived from the same region of mesoderm that produces the gonads. Endocrine tissues that secrete steroid hormones all are derived from mesoderm. The adrenal medulla is derived from ectoderm from neural crest cells that migrate to the superior pole of the kidney. Recall that neural crest cells also give rise to sympathetic ganglia and other structures of the nervous system (see Figure 14.27b on page 537).

The pancreas develops during the fifth through seventh weeks from two outgrowths of endoderm from the part of the foregut that later becomes the duodenum (see Figure 29.12c on page 1148). The two outgrowths eventually fuse to form the pancreas. The origin of the ovaries and testes is discussed in the section on the reproductive system.

The pineal gland arises during the seventh week as an outgrowth between the thalamus and colliculi of the midbrain from ectoderm associated with the diencephalon (see Figure 14.28 on page 538).

The thymus arises during the fifth week from endoderm of the third pharyngeal pouches.

30. Compare the origins of the adrenal cortex and adrenal medulla.

AGING AND THE ENDOCRINE SYSTEM

Describe the effects of aging on the endocrine system.

Although some endocrine glands shrink as we get older, their performance may or may not be compromised. Production of human growth hormone by the anterior pituitary decreases, which is one cause of muscle atrophy as aging proceeds. The thyroid gland often decreases its output of thyroid hormones with age, causing a decrease in metabolic rate, an increase in body fat, and hypothyroidism, which is seen more often in older people. Because there is less negative feedback (lower levels of thyroid hormones), the level of thyroid-stimulating hormone increases with age (see Figure 18.12).

With aging, the blood level of PTH rises, perhaps due to inadequate dietary intake of calcium. In a study of older women who took 2,400 mg/day of supplemental calcium, blood levels of PTH were as low as those of younger women. Both calcitriol and calcitonin levels are lower in older persons. Together, the rise in PTH and the fall in calcitonin level heighten the age-related decrease in bone mass that leads to osteoporosis and increased risk of fractures (see Figure 18.14).

The adrenal glands contain increasingly more fibrous tissue and produce less cortisol and aldosterone with advancing age. However, production of epinephrine and norepinephrine remains normal. The pancreas releases insulin more slowly with age, and receptor sensitivity to glucose declines. As a result, blood glucose levels in older people increase faster and return to normal more slowly than in younger individuals.

The thymus is largest in infancy. After puberty, its size begins to decrease, and thymic tissue is replaced by adipose and areolar connective tissue. In older adults, the thymus has atrophied sig-
nificantly. However, it still produces new T cells for immune responses.

The ovaries decrease in size with age, and they no longer respond to gonadotropins. The resultant decreased output of estrogens leads to conditions such as osteoporosis, high blood cholesterol, and atherosclerosis. FSH and LH levels are high due to less negative feedback inhibition of estrogens. Although testosterone production by the testes decreases with age, the effects are not usually apparent until very old age, and many elderly males can still produce active sperm in normal numbers.

**CHECKPOINT**

31. Which hormone is related to the muscle atrophy that occurs with aging?

To appreciate the many ways the endocrine system contributes to homeostasis of other body systems, examine *Focus on Homeostasis: The Endocrine System*. Next, in Chapter 19, we will begin to explore the cardiovascular system, starting with a description of the composition and functions of blood.
**Focus on Homeostasis**

<tr>
<td><strong>Reproductive systems</strong></td>
<td>Hypothalamic releasing and inhibiting hormones, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) regulate development, growth, and secretions of the gonads (ovaries and testes); estrogens and testosterone contribute to development of oocytes and sperm and stimulate development of secondary sex characteristics; prolactin promotes milk secretion in mammary glands; oxytocin causes contraction of the uterus and ejection of milk from the mammary glands.</td>
</tr>
</tbody>
</table>
Disorders of the endocrine system often involve either hyposecretion (hypo- = too little or under), inadequate release of a hormone, or hypersecretion (hyper- = too much or above), excessive release of a hormone. In other cases, the problem is faulty hormone receptors, an inadequate number of receptors, or defects in second-messenger systems. Because hormones are distributed in the blood to target tissues throughout the body, problems associated with endocrine dysfunction may also be widespread.

Pituitary Gland Disorders

Pituitary Dwarfism, Giantism, and Acromegaly

Several disorders of the anterior pituitary involve human growth hormone (hGH). Hyposecretion of hGH during the growth years slows bone growth, and the epiphyseal plates close before normal height is reached. This condition is called pituitary dwarfism. Other organs of the body also fail to grow, and the body proportions are childlike. Treatment requires administration of hGH during childhood, before the epiphyseal plates close.

Hypersecretion of hGH during childhood causes giantism, an abnormal increase in the length of long bones. The person grows to be very tall, but body proportions are about normal. Figure 18.22a shows identical twins; one brother developed giantism due to a pituitary tumor. Hypersecretion of hGH during adulthood is called acromegaly (ak'-ró-MEG-a-lē). Although hGH cannot produce further lengthening of the long bones because the epiphyseal plates are already closed, the bones of the hands, feet, cheeks, and jaws thicken and other tissues enlarge. In addition, the eyelids, lips, tongue, and nose enlarge, and the skin thickens and develops furrows, especially on the forehead and soles (Figure 18.22b).

Figure 18.22 Various endocrine disorders.

Disorders of the endocrine system often involve hyposecretion or hypersecretion of hormones.

(a) A 22-year old man with pituitary giantism shown beside his identical twin
(b) Acromegaly (excess hGH during adulthood)
(c) Goiter (enlargement of thyroid gland)
(d) Exophthalmos (excess thyroid hormones, as in Graves’ disease)
(e) Cushing’s syndrome (excess glucocorticoids)

Which endocrine disorder is due to antibodies that mimic the action of TSH?
Diabetes Insipidus
The most common abnormality associated with dysfunction of the posterior pituitary is diabetes insipidus (di-a-BE-tis in-SIP-i-dus; diabetes = overflow; insipidus = tasteless) or DI. This disorder is due to defects in antidiuretic hormone (ADH) receptors or an inability to secrete ADH. Neurogenic diabetes insipidus results from hyposecretion of ADH, usually caused by a brain tumor, head trauma, or brain surgery that damages the posterior pituitary or the hypothalamus. In nephrogenic diabetes insipidus, the kidneys do not respond to ADH. The ADH receptors may be nonfunctional, or the kidneys may be damaged. A common symptom of both forms of DI is excretion of large volumes of urine, with resulting dehydration and thirst. Bed-wetting is common in afflicted children. Because so much water is lost in the urine, a person with DI may die of dehydration if deprived of water for only a day or so.

Treatment of neurogenic diabetes insipidus involves hormone replacement, usually for life. Either subcutaneous injection or nasal spray application of ADH analogs is effective. Treatment of nephrogenic diabetes insipidus is more complex and depends on the nature of the kidney dysfunction. Restriction of salt in the diet and, paradoxically, the use of certain diuretic drugs, are helpful.

Thyroid Gland Disorders
Thyroid gland disorders affect all major body systems and are among the most common endocrine disorders. Congenital hypothyroidism, hyposecretion of thyroid hormones that is present at birth, has devastating consequences if not treated promptly. Previously termed cretinism, this condition causes severe mental retardation and stunted bone growth. At birth, the baby typically is normal because lipid-soluble maternal thyroid hormones crossed the placenta during pregnancy and allowed normal development. Most states require testing of all newborns to ensure adequate thyroid function. If congenital hypothyroidism exists, oral thyroid hormone treatment must be started soon after birth and continued for life.

Hypothyroidism during the adult years produces myxedema (mix-e-DE-ma), which occurs about five times more often in females than in males. A hallmark of this disorder is edema (accumulation of interstitial fluid) that causes the facial tissues to swell and look puffy. A person with myxedema has a slow heart rate, low body temperature, sensitivity to cold, dry hair and skin, muscular weakness, general lethargy, and a tendency to gain weight easily. Because the brain has already reached maturity, mental retardation does not occur, but the person may be less alert. Oral thyroid hormones reduce the symptoms.

The most common form of hyperthyroidism is Graves' disease, which also occurs seven to ten times more often in females than in males, usually before age 40. Graves' disease is an autoimmune disorder in which the person produces antibodies that mimic the action of thyroid-stimulating hormone (TSH). The antibodies continually stimulate the thyroid gland to grow and produce thyroid hormones. A primary sign is an enlarged thyroid, which may be two to three times its normal size. Graves' patients often have a peculiar edema behind the eyes, called exophthalmos (ek'-sof-THAL-mos), which causes the eyes to protrude (Figure 18.22d). Treatment may include surgical removal of part or all of the thyroid gland (thyroidectomy), the use of radioactive iodine (131I) to selectively destroy thyroid tissue, and the use of antithyroid drugs to block synthesis of thyroid hormone. In some places in the world, dietary iodine intake is inadequate; the resultant low level of thyroid hormone in the blood stimulates secretion of TSH, which causes thyroid gland enlargement (Figure 18.22c).

Parathyroid Gland Disorders
Hyppoparathyroidism—too little parathyroid hormone—leads to a deficiency of blood Ca2+, which causes neurons and muscle fibers to depolarize and produce action potentials spontaneously. This leads to twitches, spasms, and tetany (maintained contraction) of skeletal muscle. The leading cause of hypoparathyroidism is accidental damage to the parathyroid glands or to their blood supply during thyroidectomy surgery.

Hyperparathyroidism, an elevated level of parathyroid hormone, most often is due to a tumor of one of the parathyroid glands. An elevated level of PTH causes excessive resorption of bone matrix, raising the blood levels of calcium and phosphate ions and causing bones to become soft and easily fractured. High blood calcium level promotes formation of kidney stones. Fatigue, personality changes, and lethargy are also seen in patients with hyperparathyroidism.

Adrenal Gland Disorders
Cushing's Syndrome
Hypersecretion of cortisol by the adrenal cortex produces Cushing's syndrome (Figure 18.22e). Causes include a tumor of the adrenal gland that secretes cortisol, or a tumor elsewhere that secretes adrenocorticotropic hormone (ACTH), which in turn stimulates excessive secretion of cortisol. The condition is characterized by breakdown of muscle proteins and redistribution of body fat, resulting in spindly arms and legs accompanied by a rounded "moon face," "buffalo hump" on the back, and pendulous (hanging) abdomen. Facial skin is flushed, and the skin covering the abdomen develops stretch marks. The person also bruises easily, and wound healing is poor. The elevated level of cortisol causes hyperglycemia, osteoporosis, weakness, hypertension, increased susceptibility to infection, decreased resistance to stress, and mood swings. People who need long-term glucocorticoid therapy—for instance, to prevent rejection of a transplanted organ—may develop a cushinoid appearance.

Addison's Disease
Hypposecretion of glucocorticoids and aldosterone causes Addison's disease (chronic adrenocortical insufficiency). The majority of cases are autoimmune disorders in which antibodies cause adrenal cortex destruction or block binding of ACTH to its receptors. Pathogens, such as the bacterium that causes tuberculosis, also may trigger adrenal cortical destruction or block binding of ACTH to its receptors. Symptoms, which typically do not appear until 90% of the adrenal cortex has been destroyed, include mental lethargy, anorexia, nausea and vomiting, weight loss, hypoglycemia, and muscular weakness. Loss of aldosterone leads to elevated potassium and decreased sodium in the blood, low blood pressure, dehydration, decreased cardiac output, arrhythmias, and even cardiac arrest. The skin may have a "bronzed" appearance that often is mistaken for a suntan. Such was true in the case of President John F. Kennedy, whose Addison's disease was known to only a few while he was alive. Treatment consists of replacing glucocorticoids and mineralocorticoids and increasing sodium in the diet.

Pheochromocytomas
Usually benign tumors of the chromaffin cells of the adrenal medulla, called pheochromocytomas (fē-ō-kro'-mō-si-TÖ-mas; pheo = dusky;
**Pancreatic Islet Disorders**

The most common endocrine disorder is diabetes mellitus (MEL-i-tus; melli- = honey sweetened), caused by an inability to produce or use insulin. Diabetes mellitus is the fourth leading cause of death by disease in the United States, primarily because of its damage to the cardiovascular system. Because insulin is unavailable to aid transport of glucose into body cells, blood glucose level is high and glucose "spills" into the urine (glucosuria). Hallmarks of diabetes mellitus are the three "polys": polyuria, excessive urine production due to an inability of the kidneys to reabsorb water; polydipsia, excessive thirst; and polyphagia, excessive eating.

Both genetic and environmental factors contribute to onset of the two types of diabetes mellitus—type 1 and type 2—but the exact mechanisms are still unknown. In type 1 diabetes insulin level is low because the person's immune system destroys the pancreatic beta cells. It is also called insulin-dependent diabetes mellitus (IDDM) because insulin injections are required to prevent death. Most commonly, IDDM develops in people younger than age 20, though it persists throughout life. By the time symptoms of IDDM arise, 80–90% of the islet beta cells have been destroyed. IDDM is most common in northern Europe, especially in Finland where nearly 1% of the population develops IDDM by 15 years of age. In the United States, IDDM is 1.5–2.0 times more common in whites than in African American or Asian populations.

The cellular metabolism of an untreated type 1 diabetic is similar to that of a starving person. Because insulin is not present to aid the entry of glucose into body cells, most cells use fatty acids to produce ATP. Stores of triglycerides in adipose tissue are catabolized to yield fatty acids and glycerol. The byproducts of fatty acid breakdown—organic acids called ketones or ketone bodies—accumulate. Buildup of ketones causes blood pH to fall, a condition known as ketoacidosis. Unless treated quickly, ketoacidosis can cause death.

The breakdown of stored triglycerides also causes weight loss. As lipids are transported by the blood from storage depots to cells, lipid particles are deposited on the walls of blood vessels, leading to atherosclerosis and a multitude of cardiovascular problems, including cerebrovascular insufficiency, ischemic heart disease, peripheral vascular disease, and gangrene. A major complication of diabetes is loss of vision due either to cataracts (excessive glucose attaches to lens proteins, causing cloudiness) or to damage to blood vessels of the retina. Severe kidney problems also may result from damage to renal blood vessels.

Type 1 diabetes is treated through self-monitoring of blood glucose level (up to 7 times daily), regular meals containing 45–50% carbohydrates and less than 30% fats, exercise, and periodic insulin injections (up to 3 times a day). Several implantable pumps are available to provide insulin without the need for repeated injections. Because they lack a reliable glucose sensor, however, the person must self-monitor blood glucose level to determine insulin doses. It is also possible to successfully transplant a pancreas, but immunosuppressive drugs must then be taken for life. Another promising approach under investigation is transplantation of isolated islets in semipermeable hollow tubes. The tubes allow glucose and insulin to enter and leave but prevent entry of immune system cells that might attack the islet cells.

Type 2 diabetes, also called non-insulin-dependent diabetes mellitus (NIDDM), is much more common than type 1, representing more than 90% of all cases. Type 2 diabetes most often occurs in obese people who are over age 35. However, the number of obese children and teenagers with type 2 diabetes is increasing. Clinical symptoms are mild, and the high glucose levels in the blood often can be controlled by diet, exercise, and weight loss. Sometimes, a drug such as glyburide (Diabeta®) is used to stimulate secretion of insulin by pancreatic beta cells. Although some type 2 diabetics need insulin, many have a sufficient amount (or even a surplus) of insulin in the blood. For these people, diabetes arises not from a shortage of insulin but because target cells become less sensitive to it due to down-regulation of insulin receptors.

Hyperinsulinism most often results when a diabetic injects too much insulin. The main symptom is hypoglycemia, decreased blood glucose level, which occurs because the excess insulin stimulates too much uptake of glucose by body cells. The resulting hypoglycemia stimulates the secretion of epinephrine, glucagon, and human growth hormone. As a consequence, anxiety, sweating, tremor, increased heart rate, hunger, and weakness occur. When blood glucose falls, brain cells are deprived of the steady supply of glucose they need to function effectively. Severe hypoglycemia leads to mental disorientation, convulsions, unconsciousness, and shock. Shock due to an insulin overdose is termed insulin shock. Death can occur quickly unless blood glucose level is raised. From a clinical standpoint, a diabetic suffering from either a hyperglycemia or a hypoglycemia crisis can have very similar symptoms—mental changes, coma, seizures, and so on. It is important to quickly and correctly identify the cause of the underlying symptoms and treat them appropriately.

---

**MEDICAL TERMINOLOGY**

*Gynecomastia* (gi-ne’-ko-MAS-té-a; gyneco- = woman; mast- = breast) Excessive development of mammary glands in a male. Sometimes a tumor of the adrenal gland may secrete sufficient amounts of estrogen to cause the condition.

*Hirsutism* (HER-soo-tizm; hirsut- = shaggy) Presence of excessive body and facial hair in a male pattern, especially in women; may be due to excess androgen production due to tumors or drugs.

*Thyroid crisis (storm)* A severe state of hyperthyroidism that can be life threatening. It is characterized by high body temperature, rapid heart rate, high blood pressure, gastrointestinal symptoms (abdominal pain, vomiting, diarrhea), agitation, tremors, confusion, seizures, and possibly coma.

*Virilizing adenoma* (aden = gland; oma = tumor) Tumor of the adrenal gland that liberates excessive androgens, causing virilism (masculinization) in females. Occasionally, adrenal tumor cells liberate estrogens to the extent that a male patient develops gynecomastia. Such a tumor is called a *feminizing adenoma.*
CHAPTER 18 • THE ENDOCRINE SYSTEM

STUDY OUTLINE

Introduction (p. 642)
1. Hormones regulate the activity of smooth muscle, cardiac muscle, and some glands; alter metabolism; spur growth and development; influence reproductive processes; and participate in circadian (daily) rhythms.

Comparison of Control by the Nervous and Endocrine Systems (p. 643)
1. The nervous system controls homeostasis through nerve impulses and neurotransmitters, which act locally and quickly. The endocrine system uses hormones, which act more slowly in distant parts of the body. (See Table 18.1 on page 643.)
2. The nervous system controls neurons, muscle cells, and glandular cells; the endocrine system regulates virtually all body cells.

Endocrine Glands (p. 643)
1. Exocrine glands (sudoriferous, sebaceous, mucous, and digestive) secrete their products through ducts into body cavities or onto body surfaces. Endocrine glands secrete hormones into interstitial fluid. Then, the hormones diffuse into the blood.
2. The endocrine system consists of endocrine glands (pituitary, thyroid, parathyroid, adrenal, and pineal glands) and other hormone-secreting tissues (hypothalamus, thymus, pancreas, ovaries, testes, kidneys, stomach, liver, small intestine, skin, heart, adipose tissue, and placenta).

Hormone Activity (p. 644)
1. Hormones affect only specific target cells that have receptors to recognize (bind) a given hormone. The number of hormone receptors may decrease (down-regulation) or increase (up-regulation).
2. Circulating hormones enter the bloodstream; local hormones (paracrine and autocrine) act locally on neighboring cells.
3. Chemically, hormones are either lipid-soluble (steroids, thyroid hormones, and nitric oxide) or water-soluble (amines; peptides, proteins, and glycoproteins; and eicosanoids). (See Table 18.2 on page 647.)
4. Water-soluble hormone molecules circulate in the watery blood plasma in a “free” form (not attached to plasma proteins); most lipid-soluble hormones are bound to transport proteins synthesized by the liver.

Mechanisms of Hormone Action (p. 646)
1. Lipid-soluble steroid hormones and thyroid hormones affect cell function by altering gene expression.
2. Water-soluble hormones alter cell function by activating plasma membrane receptors, which elicit production of a second messenger that activates various enzymes inside the cell.
3. Hormonal interactions can have three types of effects: permissive, synergistic, or antagonistic.

Control of Hormone Secretion (p. 650)
1. Hormone secretion is controlled by signals from the nervous system, chemical changes in blood, and other hormones.
2. Negative feedback systems regulate the secretion of many hormones.

Hypothalamus and Pituitary Gland (p. 650)
1. The hypothalamus is the major integrating link between the nervous and endocrine systems.
2. The hypothalamus and pituitary gland regulate virtually all aspects of growth, development, metabolism, and homeostasis.
3. The pituitary gland is located in the hypophyseal fossa and is divided into the anterior pituitary (glandular portion), the posterior pituitary (nervous portion), and the pars intermedia (avascular zone in between).
4. Secretion of anterior pituitary hormones is stimulated by releasing hormones and suppressed by inhibiting hormones from the hypothalamus.
5. The blood supply to the anterior pituitary is from the superior hypophyseal arteries. Hypothalamic releasing and inhibiting hormones enter the primary plexus and flow to the secondary plexus in the anterior pituitary by the hypophyseal portal veins.
6. The anterior pituitary consists of somatotrophs that produce human growth hormone (hGH); lactotrophs that produce prolactin (PRL); corticotrophs that secrete adrenocorticotropic hormone (ACTH) and melanocyte-stimulating hormone (MSH); thyrotrophs that secrete thyroid-stimulating hormone (TSH); and gonadotrophs that synthesize follicle-stimulating hormone (FSH) and luteinizing hormone (LH). (See Tables 18.3 and 18.4 on pages 652 and 655.)
7. Human growth hormone (hGH) stimulates body growth through insulinlike growth factors (IGFs). Secretion of hGH is inhibited by GHIH (growth hormone–inhibiting hormone, or somatostatin) and promoted by GHRH (growth hormone–releasing hormone).
8. TSH regulates thyroid gland activities. Its secretion is stimulated by TRH (thyrotropin-releasing hormone) and suppressed by GHIH.
9. FSH and LH regulate the activities of the gonads—ovaries and testes. Their secretion is controlled by GnRH (gonadotropin-releasing hormone).
10. Prolactin (PRL) helps initiate milk secretion. Prolactin-inhibiting hormone (PIH) suppresses secretion of PRL; prolactin-releasing hormone (PRH) and TRH stimulate PRL secretion.
11. ACTH regulates the activities of the adrenal cortex and is controlled by CRH (corticotropin-releasing hormone).
12. Dopamine inhibits secretion of MSH.
13. The posterior pituitary contains axon terminals of neurosecretory cells whose cell bodies are in the hypothalamus.
14. Hormones made by the hypothalamus and stored in the posterior pituitary are oxytocin (OT), which stimulates contraction of the uterus and ejection of milk from the breasts, and antidiuretic hormone (ADH), which stimulates water reabsorption by the kidneys and constriction of arterioles. (See Table 18.5 on page 658.)
15. Oxytocin secretion is stimulated by uterine stretching and suckling during nursing; ADH secretion is controlled by osmotic pressure of the blood and blood volume.

Thyroid Gland (p. 658)
1. The thyroid gland is located inferior to the larynx.
2. It consists of thyroid follicles composed of follicular cells, which secrete the thyroid hormones thyroxine (T4) and triiodothyronine (T3), and parafollicular cells, which secrete calcitonin (CT).
3. Thyroid hormones are synthesized from iodine and tyrosine within thyroglobulin (TGB). They are transported in the blood bound to plasma proteins, mostly thyroxine-binding globulin (TBG).

4. Secretion is controlled by TRH from the hypothalamus and thyroid-stimulating hormone (TSH) from the anterior pituitary.

5. Thyroid hormones regulate oxygen use and metabolic rate, cellular metabolism, and growth and development.

6. Calcitonin (CT) can lower the blood level of calcium ions (Ca^{2+}) and promote deposition of Ca^{2+} into bone matrix. Secretion of CT is controlled by the Ca^{2+} level in the blood. (See Table 18.6 on page 662.)

Parathyroid Glands (p. 662)

1. The parathyroid glands are embedded in the posterior surfaces of the lateral lobes of the thyroid gland. They consist of chief cells and oxyphil cells.

2. Parathyroid hormone (PTH) regulates the homeostasis of calcium, magnesium, and phosphate ions by increasing blood calcium and magnesium levels and decreasing blood phosphate levels. PTH secretion is controlled by the level of calcium in the blood. (See Table 18.7 on page 664.)

Adrenal Glands (p. 665)

1. The adrenal glands are located superior to the kidneys. They consist of an outer adrenal cortex and inner adrenal medulla.

2. The adrenal cortex is divided into a zona glomerulosa, a zona fasciculata, and a zona reticularis; the adrenal medulla consists of chromaffin cells and large blood vessels.

3. Cortical secretions include mineralocorticoids, glucocorticoids, and androgens.

4. Mineralocorticoids (mainly aldosterone) increase sodium and water reabsorption and decrease potassium reabsorption. Secretion is controlled by the renin–angiotensin–aldosterone (RAA) pathway and by K+ level in the blood.

5. Glucocorticoids (mainly cortisol) promote protein breakdown, gluconeogenesis, and lipolysis; help resist stress; and serve as anti-inflammatory substances. Their secretion is controlled by ACTH.

6. Androgens secreted by the adrenal cortex stimulate growth of axillary and pubic hair, aid the prepubertal growth spurt, and contribute to libido.

7. The adrenal medulla secretes epinephrine and norepinephrine (NE), which are released during stress and produce effects similar to sympathetic responses. (See Table 18.8 on page 669.)

Pancreatic Islets (p. 669)

1. The pancreas lies in the curve of the duodenum. It has both endocrine and exocrine functions.

2. The endocrine portion consists of pancreatic islets or islets of Langerhans, made up of four types of cells: alpha, beta, delta, and F cells.

3. Alpha cells secrete glucagon, beta cells secrete insulin, delta cells secrete somatostatin, and F cells secrete pancreatic polypeptide.

4. Glucagon increases blood glucose level; insulin decreases blood glucose level. Secretion of both hormones is controlled by the level of glucose in the blood. (See Table 18.9 on page 672.)

Ovaries and Testes (p. 673)

1. The ovaries are located in the pelvic cavity and produce estrogens, progesterone, and inhibit. These sex hormones govern the development and maintenance of female secondary sex characteristics, reproductive cycles, pregnancy, lactation, and normal female reproductive functions. (See Table 18.10 on page 673.)

2. The testes lie inside the scrotum and produce testosterone and inhibit. These sex hormones govern the development and maintenance of male secondary sex characteristics and normal male reproductive functions. (See Table 18.10 on page 673.)

Pineal Gland (p. 673)

1. The pineal gland is attached to the roof of the third ventricle of the brain. It consists of secretory cells called pinealocytes, neuroglia, and endings of sympathetic postganglionic axons.

2. The pineal gland secretes melatonin, which contributes to setting the body’s biological clock (controlled in the suprachiasmatic nucleus). During sleep, plasma levels of melatonin increase.

Thymus (p. 674)

1. The thymus secretes several hormones related to immunity.

2. Thymosin, thymic humoral factor (THF), thymic factor (TF), and thymopoietin promote the maturation of T cells.

Other Endocrine Tissues and Organs, Eicosanoids, and Growth Factors (p. 674)

1. Body tissues other than those normally classified as endocrine glands contain endocrine tissue and secrete hormones, including the gastrointestinal tract, placenta, kidneys, skin, and heart. (See Table 18.11 on page 674.)

2. Prostaglandins and leukotrienes are eicosanoids that act as local hormones in most body tissues.

3. Growth factors are local hormones that stimulate cell growth and division. (See Table 18.12 on page 675.)

The Stress Response (p. 675)

1. Productive stress is termed eustress, and harmful stress is termed distress.

2. If stress is extreme, it triggers the stress response (general adaptation syndrome), which occurs in three stages: the fight-or-flight response, resistance reaction, and exhaustion.

3. The stimuli that produce the stress response are called stressors. Stressors include surgery, poisons, infections, fever, and strong emotional responses.

4. The fight-or-flight response is initiated by nerve impulses from the hypothalamus to the sympathetic division of the autonomic nervous system and the adrenal medulla. This response rapidly increases circulation, promotes ATP production, and decreases nonessential activities.

5. The resistance reaction is initiated by releasing hormones secreted by the hypothalamus, most importantly CRH, TRH, and GHRH. Resistance reactions are longer lasting and accelerate breakdown reactions to provide ATP for countering stress.

6. Exhaustion results from depletion of body resources during the resistance stage.
7. Stress may trigger certain diseases by inhibiting the immune system. An important link between stress and immunity is interleukin-1, produced by macrophages; it stimulates secretion of ACTH.

**Development of the Endocrine System (p. 678)**

1. The development of the endocrine system is not as localized as in other systems because endocrine organs develop in widely separated parts of the embryo.
2. The pituitary gland, adrenal medulla, and pineal gland develop from ectoderm; the adrenal cortex develops from mesoderm; and the thyroid gland, parathyroid glands, pancreas, and thymus develop from endoderm.

**SELF-QUIZ QUESTIONS**

**Fill in the blanks in the following statements.**

1. The three stages of the stress response or general adaptation syndrome, in order of occurrence, are ______, ______, and ______.
2. The ______ is the major integrating link between the nervous and endocrine systems, acts as an endocrine gland itself, and helps control the stress response.
3. Down-regulation makes a target cell ______ sensitive to a hormone while up-regulation makes a target cell ______ sensitive to a hormone.

**Indicate whether the following statements are true or false.**

4. If the effect of two or more hormones acting together is greater than the sum of each acting alone, then the two hormones are said to have a permissive effect.
5. In the direct gene activation method of hormone action, the hormone enters the target cell and binds to an intracellular receptor. The activated receptor–hormone complex then alters gene expression to produce the protein that causes the physiological responses that are characteristic of the hormone.

**Choose the one best answer to the following questions.**

6. Which of the following comparisons are true? (1) Nerve impulses produce their effects quickly; hormonal responses generally are slower. (2) Nervous system effects are brief; endocrine system effects are longer lasting. (3) The nervous system controls homeostasis through mediator molecules called neurotransmitters; the endocrine system works through mediator molecules called hormones. (4) The nervous system can stimulate or inhibit the release of hormones; some hormones are released by neurons as neurotransmitters. (5) Transmitters are local hormones that circulate rapidly through the blood; hormones are released in low concentrations but can produce large effects in the target cells because of amplification; transmitters cannot bind to transport proteins in order to circulate in the blood; (4) may be released in low concentrations but can produce large effects in the target cells because of amplification; (5) can regulate the responsiveness of the target tissue by controlling the number of receptor sites for the hormone.

(a) 1, 2, 3, 4, and 5 (b) 1, 2, 3, 4, and 5 (c) 2, 3, 4, and 5 (d) 2, 3, 4, and 5 (e) 1, 4, and 5

7. Insulin and thyroxine arrive at a target organ at the same time. Thyroxine causes an effect on the organ but insulin does not. Why?

(a) Thyroxine is a lipid-soluble hormone and insulin is not.
(b) The target cells in the organ have up-regulated for thyroxine.
(c) Thyroxine is a local hormone and insulin is a circulating hormone.
(d) Thyroxine inhibits the action of insulin.
(e) The organ’s cells have receptors for thyroxine but not for insulin.

8. Which of the following is not a category of water-soluble hormones?

(a) peptides (b) amines (c) eicosanoids (d) steroids (e) proteins

9. Place in correct order the action of a water-soluble hormone on its target cell. (1) The hormone binds to a membrane receptor. (2) Enzymes catalyze reactions that produce a physiological response attributed to the hormone. (3) Transcription factors activate gene expression to produce the protein that causes the physiological response that is characteristic of the hormone. (4) Hormones phosphorylate cellular proteins. (5) The hormone-receptor complex activates G proteins. (6) Cyclic AMP activates protein kinases.

(a) 1, 2, 3, 4, 5, 6 (b) 3, 1, 5, 6, 4, 2 (c) 5, 1, 4, 2, 3, 6 (d) 3, 4, 5, 1, 6, 2 (e) 6, 3, 5, 1, 4, 2

10. Hormones (1) generally utilize negative feedback mechanisms to regulate their secretion; (2) will only affect target cells far removed from the hormone-producing secretory cells; (3) must bind to transport proteins in order to circulate in the blood; (4) may be released in low concentrations but can produce large effects in the target cells because of amplification; (5) can regulate the responsiveness of the target tissue by controlling the number of receptor sites for the hormone.

(a) 1, 2, 3 (b) 1, 2, 4, and 5 (c) 2, 3, 4 (d) 2, 3, 4, and 5 (e) 1, 4, and 5

11. The pituitary gland (1) is located in the sella turcica, (2) is linked to the hypothalamus by the infundibulum, (3) has a posterior portion that contains axon terminals from hypothalamic neurosecretory cells, (4) produces releasing and inhibiting hormones, (5) has a vascular connection with the hypothalamus known as the hypothalamic portal system.

(a) 1, 2, and 3 (b) 2, 3, 4, and 5 (c) 2, 3, 4, and 5 (d) 1, 2, 3, 4, and 5 (e) 2, 4, and 5

12. The class of adrenal gland hormones that provides resistance to stress, produces anti-inflammatory effects, and promotes normal metabolism to ensure adequate quantities of ATP is

(a) glucocorticoids. (b) mineralocorticoids. (c) androgens. (d) catecholamines. (e) gonadocorticoids.
Self-Quiz Questions

13. Match the following:
   (a) increases blood Ca^{2+} level
   (b) increases blood glucose level
   (c) decreases blood Ca^{2+} level
   (d) decreases blood glucose level
   (e) initiates and maintains milk secretion by the mammary glands
   (f) regulates the body’s biological clock
   (g) stimulates sex hormone production; triggers ovulation
   (h) augments fight-or-flight responses
   (i) regulates metabolism and resistance to stress
   (j) helps control water and electrolyte homeostasis
   (k) suppresses release of FSH
   (l) inhibits water loss through the kidneys
   (m) stimulates egg and sperm formation
   (n) promotes T cell maturation
   (o) stimulates protein synthesis, inhibits protein breakdown, stimulates lipolysis, and retards use of glucose for ATP production
   (p) inhibits skin pigmentation when present in excess
   (q) stimulates synthesis and release of T₃ and T₄
   (r) enhances uterine contractions during labor; stimulates milk ejection
   (s) stimulates and inhibits secretion of anterior pituitary hormones
   (t) increases skin pigmentation when present in excess
   (u) stimulates synthesis and release of T₁ and T₂
   (v) local hormones involved in inflammation, smooth muscle contraction, blood flow, and inflammation

14. Match the following hormone-secreting cells to the hormone(s) they release:
   (a) ACTH and MSH
   (b) TSH
   (c) glucagon
   (d) PTH
   (e) glucocorticoids
   (f) calcitonin
   (g) insulin
   (h) androgens
   (i) progesterone
   (j) FSH and LH
   (k) epinephrine and norepinephrine
   (l) hGH
   (m) testosterone
   (n) mineralocorticoids
   (o) thyroxine and triiodothyronine
   (p) PRL

15. Match the endocrine disorder to the problem that produced the disorder:
   (a) hyposecretion of insulin or down-regulation of insulin receptors
   (b) hypersecretion of hGH before closure of epiphyseal plates
   (c) hyposecretion of thyroid hormone that is present at birth
   (d) hypersecretion of glucocorticoids
   (e) hyposecretion of hGH before closure of epiphyseal plates
   (f) hypersecretion of epinephrine and norepinephrine
   (g) hypersecretion of hGH after closure of epiphyseal plates
   (h) hypersecretion of glucocorticoids and aldosterone
   (i) hyposecretion of ADH
   (j) hypersecretion of melatonin
   (k) hyposecretion of thyroid hormone in adults
   (l) hyperthyroidism, an autoimmune disease
CRITICAL THINKING QUESTIONS

1. Amanda hates her new student ID photo. Her hair looks dry, the extra weight that she's gained shows, and her neck looks fat. In fact, there’s an odd butterfly shaped swelling across the front of her neck, under her chin. Amanda’s also been feeling very tired and mentally “dull” lately, but she figures all new A&P students feel that way. Should she visit the clinic or just wear turtlenecks?

2. Amanda (from question 1 above) goes to the clinic and blood is drawn. The results show that her T₄ levels are low and her TSH levels are low. Later she is given a TSH stimulation test in which TSH is injected and the T₄ levels are monitored. After TSH injection, her T₄ levels rise. Does Amanda have problems with her pituitary or with her thyroid gland? How did you come to your conclusion?

3. Mr. Hernandez visited his doctor complaining that he is constantly thirsty and is “in the bathroom day and night” relieving his bladder. The doctor ordered blood and urine tests to check for glucose and ketones, which were all negative. What is the doctor’s diagnosis of Mr. Hernandez, and what gland(s) or organ(s) is(are) involved?

18.1 Secretions of endocrine glands diffuse into interstitial fluid and then into the blood; exocrine secretions flow into ducts that lead into body cavities or to the body surface.

18.2 In the stomach, histamine is a paracrine because it acts on nearby parietal cells without entering the blood.

18.3 The receptor–hormone complex alters gene expression by turning specific genes of nuclear DNA on or off.

18.4 Cyclic AMP is termed a second messenger because it translates the presence of the first messenger, the water-soluble hormone, into a response inside the cell.

18.5 The hypophyseal portal veins carry blood from the median eminence of the hypothalamus, where hypothalamic releasing and inhibiting hormones are secreted, to the anterior pituitary, where these hormones act.

18.6 Thyroid hormones suppress secretion of TSH by thyrotrophs and of TRH by hypothalamic neurosecretory cells; gonadal hormones suppress secretion of FSH and LH by gonadotrophs and of GnRH by hypothalamic neurosecretory cells.

18.7 Excess levels of hGH would cause hyperglycemia.

18.8 Functionally, both the hypothalamohypophyseal tract and the hypophyseal portal veins carry hypothalamic hormones to the pituitary gland. Structurally, the tract is composed of axons of neurons that extend from the hypothalamus to the posterior pituitary; the portal veins are blood vessels that extend from the hypothalamus to the anterior pituitary.

18.9 Absorption of a liter of water in the intestines would decrease the osmotic pressure of your blood plasma, turning off secretion of ADH and decreasing the ADH level in your blood.

18.10 Follicular cells secrete T₃ and T₄, also known as thyroid hormones. Parafollicular cells secrete calcitonin.

18.11 The storage form of thyroid hormones is thyroglobulin.

18.12 Lack of iodine in the diet → diminished production of T₃ and T₄ → increased release of TSH → growth (enlargement) of the thyroid gland → goiter.

18.13 Parafollicular cells of the thyroid gland secrete calcitonin; chief (principal) cells of the parathyroid gland secrete PTH.

18.14 Target tissues for PTH are bones and the kidneys; target tissue for CT is bone; target tissue for calcitriol is the GI tract.

18.15 The adrenal glands are superior to the kidneys in the retroperitoneal space.

18.16 Angiotensin II acts to constrict blood vessels by causing contraction of vascular smooth muscle, and it stimulates secretion of aldosterone (by zona glomerulosa cells of the adrenal cortex), which in turn causes the kidneys to conserve water and thereby increase blood volume.

18.17 A transplant recipient who takes prednisone will have low blood levels of ACTH and CRH due to negative feedback suppression of the anterior pituitary and hypothalamus by the prednisone.

18.18 The pancreas is both an endocrine and an exocrine gland.

18.19 Glycogenolysis is the conversion of glycogen into glucose and therefore it increases blood glucose level.

18.20 Homeostasis maintains controlled conditions typical of a normal internal environment; the stress response resets controlled conditions at a different level to cope with various stressors.

18.21 The pituitary gland and the adrenal glands both include tissues having two different embryological origins.

18.22 Antibodies that mimic the action of TSH are produced in Graves’ disease.
BLOOD AND HOMEOSTASIS  Blood contributes to homeostasis by transporting oxygen, carbon dioxide, nutrients, and hormones to and from your body’s cells. It helps regulate body pH and temperature, and provides protection against disease through phagocytosis and the production of antibodies.

The cardiovascular system (cardio- = heart; vascular = blood vessels) consists of three interrelated components: blood, the heart, and blood vessels. The focus of this chapter is blood; the next two chapters will examine the heart and blood vessels, respectively. Blood transports various substances, helps regulate several life processes, and affords protection against disease. For all of its similarities in origin, composition, and functions, blood is as unique from one person to another as are skin, bone, and hair. Health-care professionals routinely examine and analyze its differences through various blood tests when trying to determine the cause of different diseases. The branch of science concerned with the study of blood, blood-forming tissues, and the disorders associated with them is hematology (hēm-a-TOL-ē-jē; hema- or hemato- = blood; -logy = study of).
Functions and Properties of Blood

Objectives
- Describe the functions of blood.
- Describe the physical characteristics and principal components of blood.

Most cells of a multicellular organism cannot move around to obtain oxygen and nutrients or eliminate carbon dioxide and other wastes. Instead, these needs are met by two fluids: blood and interstitial fluid. Blood is a connective tissue composed of a liquid extracellular matrix called blood plasma that dissolves and suspends various cells and cell fragments. Interstitial fluid is the fluid that bathes body cells (see Figure 27.1 on page 1063) and is constantly renewed by the blood. Blood transports oxygen from the lungs and nutrients from the gastrointestinal tract, which diffuse from the blood into the interstitial fluid and then into body cells. Carbon dioxide and other wastes move in the reverse direction, from body cells to interstitial fluid to blood. Blood then transports the wastes to various organs—the lungs, kidneys, and skin—for elimination from the body.

Functions of Blood

Blood, which is a liquid connective tissue, has three general functions:

1. Transportation. As you just learned, blood transports oxygen from the lungs to the cells of the body and carbon dioxide from the body cells to the lungs for exhalation. It carries nutrients from the gastrointestinal tract to body cells and hormones from endocrine glands to other body cells. Blood also transports heat and waste products to various organs for elimination from the body.

2. Regulation. Circulating blood helps maintain homeostasis of all body fluids. Blood helps regulate pH through the use of buffers. It also helps adjust body temperature through the heat-absorbing and coolant properties of the water (see page 40) in blood plasma and its variable rate of flow through the skin, where excess heat can be lost from the blood to the environment. In addition, blood osmotic pressure influences the water content of cells, mainly through interactions of dissolved ions and proteins.

3. Protection. Blood can clot, which protects against its excessive loss from the cardiovascular system after an injury. In addition, its white blood cells protect against disease by carrying on phagocytosis. Several types of blood proteins, including antibodies, interferons, and complement, help protect against disease in a variety of ways.

Physical Characteristics of Blood

Blood is denser and more viscous (thicker) than water and feels slightly sticky. The temperature of blood is 38°C (100.4°F), about 1°C higher than oral or rectal body temperature, and it has a slightly alkaline pH ranging from 7.35 to 7.45. The color of blood varies with its oxygen content. When it has a high oxygen content, it is bright red. When it has a low oxygen content, it is dark red. Blood constitutes about 20% of extracellular fluid, amounting to 8% of the total body mass. The blood volume is 5 to 6 liters (1.5 gal) in an average-sized adult male and 4 to 5 liters (1.2 gal) in an average-sized adult female. The difference in volume is due to differences in body size. Several hormones, regulated by negative feedback, ensure that blood volume and osmotic pressure remain relatively constant. Especially important are the hormones aldosterone, antidiuretic hormone, and atrial natriuretic peptide, which regulate how much water is excreted in the urine (see pages 1065–1066).

Clinical Connection Withdrawing Blood

Blood samples for laboratory testing may be obtained in several ways. The most common procedure is venipuncture, withdrawal of blood from a vein using a needle and collecting tube, which contains various additives. A tourniquet is wrapped around the arm above the venipuncture site, which causes blood to accumulate in the vein. This increased blood volume makes the vein stand out. Opening and closing the fist further causes it to stand out, making the venipuncture more successful. A common site for venipuncture is the median cubital vein anterior to the elbow (see Figure 21.25b on page 808). Another method of withdrawing blood is through a finger or heel stick. Diabetic patients who monitor their daily blood sugar typically perform a finger stick, and it is often used for drawing blood from infants and children. In an arterial stick, blood is withdrawn from an artery; this test is used to determine the level of oxygen in oxygenated blood.

Components of Blood

Blood has two components: (1) blood plasma, a watery liquid extracellular matrix that contains dissolved substances, and (2) formed elements, which are cells and cell fragments. If a sample of blood is centrifuged (spun) in a small glass tube, the cells sink to the bottom of the tube while the lighter-weight plasma forms a layer on top (Figure 19.1a). Blood is about 45% formed elements and 55% blood plasma. Normally, more than 99% of the formed elements are cells named for their red color—red blood cells (RBCs). Pale, colorless white blood cells (WBCs) and platelets occupy less than 1% of the formed elements. Because they are less dense than red blood cells but more dense than blood plasma, they form a very thin buffy coat layer between the packed RBCs and plasma in centrifuged blood. Figure 19.1b shows the composition of blood plasma and the numbers of the various types of formed elements in blood.

Blood Plasma

When the formed elements are removed from blood, a straw-colored liquid called blood plasma (or simply plasma) is left. Blood plasma is about 91.5% water and 8.5% solutes, most of which (7% by weight) are proteins. Some of the proteins in blood plasma are also found elsewhere in the body, but those...
Figure 19.1 Components of blood in a normal adult.

Blood is a connective tissue that consists of blood plasma (liquid) plus formed elements (red blood cells, white blood cells, and platelets).

**Functions of Blood**

1. Transports oxygen, carbon dioxide, nutrients, hormones, heat, and wastes.
2. Regulates pH, body temperature, and water content of cells.
3. Protects against blood loss through clotting, and against disease through phagocytic white blood cells and antibodies.

What is the approximate volume of blood in your body?
confined to blood are called **plasma proteins**. Among other functions, these proteins play a role in maintaining proper blood osmotic pressure, which is an important factor in the exchange of fluids across capillary walls (discussed in Chapter 21).

Hepatocytes (liver cells) synthesize most of the plasma proteins, which include the **albumins** (54% of plasma proteins), **globulins** (38%), and **fibrinogen** (7%). Their functions are given in Table 19.1. Certain blood cells develop into cells that produce gamma globulins, an important type of globulin. These plasma proteins are also called **antibodies** or **immunoglobulins** because they are produced during certain immune responses. Foreign substances (antigens) such as bacteria and viruses stimulate production of millions of different antibodies. An antibody binds specifically to the antigen that stimulated its production and thus disables the invading antigen.

Besides proteins, other solutes in plasma include electrolytes, nutrients, regulatory substances such as enzymes and hormones, gases, and waste products such as urea, uric acid, creatinine, ammonia, and bilirubin.

Table 19.1 describes the chemical composition of blood plasma.

### Formed Elements

The formed elements of the blood include three principal components: **red blood cells (RBCs)**, **white blood cells (WBCs)**, and **platelets** (Figure 19.2). RBCs and WBCs are whole cells; platelets are cell fragments. RBCs and platelets have just a few roles, but WBCs have a number of specialized functions. Several distinct types of WBCs—neutrophils, lymphocytes, monocytes, eosinophils, and basophils—each with a unique microscopic appearance, carry out these functions, which are discussed later in this chapter.

The percentage of total blood volume occupied by RBCs is called the **hematocrit** (he-MAT-ö-krit); a hematocrit of 40 indicates that 40% of the volume of blood is composed of RBCs. The normal range of hematocrit for adult females is 38–46% (average = 42); for adult males, it is 40–54% (average = 47). The hormone testosterone, present in much higher concentration in males than in females, stimulates synthesis of erythropoietin (EPO), the hormone that in turn stimulates production of RBCs. Thus, testosterone contributes to higher hematocrits in males. Lower values in women during their reproductive years also may be due to excessive loss of blood during menstruation. A significant drop in hematocrit indicates anemia, a lower-than-
normal number of RBCs. In polycythemia the percentage of RBCs is abnormally high, and the hematocrit may be 65% or higher. This raises the viscosity of blood, which increases the resistance to flow and makes the blood more difficult for the heart to pump. Increased viscosity also contributes to high blood pressure and increased risk of stroke. Causes of polycythemia include abnormal increases in RBC production, tissue hypoxia, dehydration, and blood doping or the use of EPO by athletes.

CHECKPOINT
1. In what ways is blood plasma similar to interstitial fluid? How does it differ?
2. What substances does blood transport?
3. How many kilograms or pounds of blood are there in your body?
4. How does the volume of blood plasma in your body compare to the volume of fluid in a two-liter bottle of Coke?
5. List the formed elements in blood plasma and describe their functions.
6. What is the significance of lower-than-normal or higher-than-normal hematocrit?

FORMATION OF BLOOD CELLS

OBJECTIVE
• Explain the origin of blood cells.

Although some lymphocytes have a lifetime measured in years, most formed elements of the blood last only hours, days, or weeks, and must be replaced continually. Negative feedback systems regulate the total number of RBCs and platelets in circulation, and their numbers normally remain steady. The abundance of the different types of WBCs, however, varies in response to challenges by invading pathogens and other foreign antigens.

The process by which the formed elements of blood develop is called hemopoiesis (hē-mō-poy-E-sis; -poiesis = making) or hematopoiesis. Before birth, hemopoiesis first occurs in the yolk sac of an embryo and later in the liver, spleen, thymus, and lymph nodes of a fetus. Red bone marrow becomes the primary site of hemopoiesis in the last three months before birth, and continues as the source of blood cells after birth and throughout life.

Red bone marrow is a highly vascularized connective tissue located in the microscopic spaces between trabeculae of spongy bone tissue. It is present chiefly in bones of the axial skeleton, pectoral and pelvic girdles, and the proximal epiphyses of the humerus and femur. About 0.05–0.1% of red bone marrow cells are derived from mesenchyme and are called pluripotent stem cells (ploo-RIP-ō-tent; pluri- = several) or hemocytoblasts. These cells have the capacity to develop into many different types of cells (Figure 19.3). In newborns all bone marrow is red and thus active in blood cell production. As an individual grows and in adulthood, the rate of blood cell formation decreases; the red bone marrow in the medullary (marrow) cavity of long bones becomes inactive and is replaced by yellow bone marrow, which is largely fat cells. Under certain conditions, such as severe bleeding, yellow bone marrow can revert to red bone marrow by extension of red bone marrow into yellow bone marrow and repopulation of yellow bone marrow by pluripotent stem cells.

Figure 19.2 Scanning electron micrograph and photomicrograph of the formed elements of blood.

- The formed elements of blood are red blood cells (RBCs), white blood cells (WBCs), and platelets.
From which connective tissue cells do pluripotent stem cells develop?

**CLINICAL CONNECTION | Bone Marrow Examination**

Sometimes a sample of red bone marrow must be obtained in order to diagnose certain blood disorders, such as leukemia and severe anemias. **Bone marrow examination** may involve **bone marrow aspiration** (withdrawal of a small amount of red bone marrow with a fine needle and syringe) or a **bone marrow biopsy** (removal of a core of red bone marrow with a larger needle).

Both types of samples are usually taken from the iliac crest of the hip bone, although samples are sometimes aspirated from the sternum. In young children, bone marrow samples are taken from a vertebra or tibia (shin bone). The tissue or cell sample is then sent to a pathology lab for analysis. Specifically, laboratory technicians look for signs of neoplastic (cancer) cells or other diseased cells to assist in diagnosis.

Stem cells in red bone marrow reproduce themselves, proliferate, and differentiate into cells that give rise to blood cells, macrophages, reticular cells, mast cells, and adipocytes. Some of the stem cells can also form osteoblasts, chondroblasts, and muscle cells, and someday may be used as a source of bone, car-

---

**Figure 19.3** Origin, development, and structure of blood cells. Some of the generations of some cell lines have been omitted. Blood cell production, called hemopoiesis, occurs mainly in red bone marrow after birth.

**CHAPTER 19 • THE CARDIOVASCULAR SYSTEM: THE BLOOD**
myeloid stem cells

The reticular cells produce reticular fibers, which form the stroma (framework) that supports red bone marrow cells. Once blood cells are produced in red bone marrow, they enter the bloodstream through sinusoids (also called sinuses), enlarged and leaky capillaries that surround red bone marrow cells and fibers.

With the exception of lymphocytes, formed elements do not divide once they leave red bone marrow.

In order to form blood cells, pluripotent stem cells in red bone marrow produce two further types of stem cells, which have the capacity to develop into several types of cells. These stem cells are called myeloid stem cells and lymphoid stem cells. Myeloid stem cells begin their development in red bone marrow and give rise to red blood cells, platelets, monocytes, neutrophils, eosinophils, and basophils. Lymphoid stem cells begin their development in red bone marrow but complete it in lymphatic tissues; they give rise to lymphocytes. Although the various stem cells have distinctive cell identity markers in their plasma membranes, they cannot be distinguished histologically and resemble lymphocytes.

During hemopoiesis, some of the myeloid stem cells differentiate into progenitor cells (prō-JEN-i-tor). Other myeloid stem cells and the lymphoid stem cells develop directly into precursor cells (described shortly). Progenitor cells are no longer capable of reproducing themselves and are committed to giving rise to more specific elements of blood. Some progenitor cells are known as colony-forming units (CFUs). Following the CFU designation is an abbreviation that indicates the mature elements in blood that they will produce: CFU–E ultimately produces erythrocytes (red blood cells), CFU–Meg produces megakaryocytes, the source of platelets, and CFU–GM ultimately produces granulocytes (specifically, neutrophils) and monocytes (see Figure 19.3). Progenitor cells, like stem cells, resemble lymphocytes and cannot be distinguished by their microscopic appearance alone.

In the next generation, the cells are called precursor cells, also known as blasts. Over several cell divisions they develop into the actual formed elements of blood. For example, monoblasts develop into monocytes, eosinophilic myeloblasts develop into eosinophils, and so on. Precursor cells have recognizable microscopic appearances.

Several hormones called hemopoietic growth factors regulate the differentiation and proliferation of particular progenitor cells. Erythropoietin (e-rith’-ró-POY-e-tin) or EPO increases the number of red blood cell precursors. EPO is produced primarily by cells in the kidneys that lie between the kidney tubules (peritubular interstitial cells). With renal failure, EPO release slows and RBC production is inadequate. Thrombopoietin (throm’-bó-POY-e-tin) or TPO is a hormone produced by the liver that stimulates the formation of platelets (thrombocytes) from megakaryocytes. Several different cytokines regulate development of different blood cell types. Cytokines are small glycoproteins that are typically produced by cells such as red bone marrow cells, leukocytes, macrophages, fibroblasts, and endothelial cells. They generally act as local hormones (autocrines or paracrines; see Chapter 18). Cytokines stimulate proliferation of progenitor cells in red bone marrow and regulate the activities of cells involved in nonspecific defenses (such as phagocytes) and immune responses (such as B cells and T cells). Two important families of cytokines that stimulate white blood cell formation are colony-stimulating factors (CSFs) and interleukins.

### Clinical Connection: Medical Uses of Hemopoietic Growth Factors

Hemopoietic growth factors made available through recombinant DNA technology hold tremendous potential for medical uses when a person’s natural ability to form new blood cells is diminished or defective. The artificial form of erythropoietin (Epoetin alfa) is very effective in treating the diminished red blood cell production that accompanies end-stage kidney disease. Granulocyte-macrophage colony-stimulating factor and granulocyte CSF are given to stimulate white blood cell formation in cancer patients who are undergoing chemotherapy, which kills red bone marrow cells as well as cancer cells because both cell types are undergoing mitosis. (Recall that white blood cells help protect against disease.) Thrombopoietin shows great promise for preventing the depletion of platelets, which are needed to help blood clot, during chemotherapy. CSFs and thrombopoietin also improve the outcome of patients who receive bone marrow transplants. Hemopoietic growth factors are also used to treat thrombocytopenia in neonates, other clotting disorders, and various types of anemia. Research on these medications is ongoing and shows a great deal of promise.

### Checkpoint

7. Which hemopoietic growth factors regulate differentiation and proliferation of CFU–E and formation of platelets from megakaryocytes?

8. Describe the formation of platelets from pluripotent stem cells, including the influence of hormones.

## Red Blood Cells

### Objective

Describe the structure, functions, life cycle, and production of red blood cells.

Red blood cells (RBCs) or erythrocytes (e-RITH-ró-síts; erythro- = red; -cyte = cell) contain the oxygen-carrying protein hemoglobin, which is a pigment that gives whole blood its red color. A healthy adult male has about 5.4 million red blood cells per microliter ($\mu$L) of blood,* and a healthy adult female has about 4.8 million. (One drop of blood is about 50 $\mu$L.) To maintain normal numbers of RBCs, new mature cells must enter the circulation at the astonishing rate of at least 2 million per second, a pace that balances the equally high rate of RBC destruction.

*1 $\mu$L = 1 mm³ = $10^{-6}$ liter.
RBC Anatomy

RBCs are biconcave discs with a diameter of 7–8 µm (Figure 19.4a). Mature red blood cells have a simple structure. Their plasma membrane is both strong and flexible, which allows them to deform without rupturing as they squeeze through narrow capillaries. As you will see later, certain glycolipids in the plasma membrane of RBCs are antigens that account for the various blood groups such as the ABO and Rh groups. RBCs lack a nucleus and other organelles and can neither reproduce nor carry on extensive metabolic activities. The cytosol of RBCs contains hemoglobin molecules; these important molecules are synthesized before loss of the nucleus during RBC production and constitute about 33% of the cell’s weight.

RBC Physiology

Red blood cells are highly specialized for their oxygen transport function. Because mature RBCs have no nucleus, all their internal space is available for oxygen transport. Because RBCs lack mitochondria and generate ATP anaerobically (without oxygen), they do not use up any of the oxygen they transport. Even the shape of an RBC facilitates its function. A biconcave disc has a much greater surface area for the diffusion of gas molecules into and out of the RBC than would, say, a sphere or a cube.

Each RBC contains about 280 million hemoglobin molecules. A hemoglobin molecule consists of a protein called globin, composed of four polypeptide chains (two alpha and two beta chains); a ringlike nonprotein pigment called a heme (Figure 19.4b) is bound to each of the four chains. At the center of each heme ring is an iron ion (Fe²⁺) that can combine reversibly with

one oxygen molecule (Figure 19.4c), allowing each hemoglobin molecule to bind four oxygen molecules. Each oxygen molecule picked up from the lungs is bound to an iron ion. As blood flows through tissue capillaries, the iron–oxygen reaction reverses. Hemoglobin releases oxygen, which diffuses first into the interstitial fluid and then into cells.

Hemoglobin also transports about 23% of the total carbon dioxide, a waste product of metabolism. Blood flowing through tissue capillaries picks up carbon dioxide, some of which combines with amino acids in the globin part of hemoglobin. As blood flows through the lungs, the carbon dioxide is released from hemoglobin and then exhaled.

In addition to its key role in transporting oxygen and carbon dioxide, hemoglobin also plays a role in the regulation of blood flow and blood pressure. The gaseous hormone nitric oxide (NO), produced by the endothelial cells that line blood vessels, binds to hemoglobin. Under some circumstances, hemoglobin releases NO. The released NO causes vasodilation, an increase in blood vessel diameter that occurs when the smooth muscle in the vessel wall relaxes. Vasodilation improves blood flow and enhances oxygen delivery to cells near the site of NO release.

RBC Life Cycle

Red blood cells live only about 120 days because of the wear and tear their plasma membranes undergo as they squeeze through blood capillaries. Without a nucleus and other organelles, RBCs cannot synthesize new components to replace damaged ones. The plasma membrane becomes more fragile with age, and the cells are more likely to burst, especially as they squeeze through narrow channels in the spleen. Ruptured

Figure 19.4 The shapes of a red blood cell (RBC) and a hemoglobin molecule. In (b), note that each of the four polypeptide chains of a hemoglobin molecule (blue) has one heme group (gold), which contains an iron ion (Fe²⁺), shown in red.

How many molecules of O₂ can one hemoglobin molecule transport?
Red blood cells are removed from circulation and destroyed by fixed phagocytic macrophages in the spleen and liver, and the breakdown products are recycled, as follows (Figure 19.5):

1. Macrophages in the spleen, liver, or red bone marrow phagocytize ruptured and worn-out red blood cells.
2. The globin and heme portions of hemoglobin are split apart.
3. Globin is broken down into amino acids, which can be reused to synthesize other proteins.
4. Iron is removed from the heme portion in the form of Fe³⁺, which associates with the plasma protein transferrin (trans-FER-in; trans- = across; ferr- = iron), a transporter for Fe³⁺ in the bloodstream.
5. In muscle fibers, liver cells, and macrophages of the spleen and liver, Fe³⁺ detaches from transferrin and attaches to an iron-storage protein called ferritin.
6. Upon release from a storage site or absorption from the gastrointestinal tract, Fe³⁺ reattaches to transferrin.
7. The Fe³⁺-transferrin complex is then carried to red bone marrow, where RBC precursor cells take it up through receptor-mediated endocytosis (see Figure 3.12 on page 74) for use in hemoglobin synthesis. Iron is needed for the heme portion of the hemoglobin molecule, and amino acids are needed for the globin portion. Vitamin B₁₂ is also needed for the synthesis of hemoglobin.

8. Erythropoiesis in red bone marrow results in the production of red blood cells, which enter the circulation.
9. When iron is removed from heme, the non-iron portion of heme is converted to biliverdin (bil’-i-VER-din), a green pigment, and then into bilirubin (bil’-i-ROO-bin), a yellow-orange pigment.
10. Bilirubin enters the blood and is transported to the liver.
11. Within the liver, bilirubin is released by liver cells into bile, which passes into the small intestine and then into the large intestine.
12. In the large intestine, bacteria convert bilirubin into urobilinogen (ür-ō-bi-LIN-o-jen).
13. Some urobilinogen is absorbed back into the blood, converted to a yellow pigment called urobilin (ür-ō-BĪ-lin), and excreted in urine.
14. Most urobilinogen is eliminated in feces in the form of a brown pigment called stercobilin (ster’-kō-BĪ-lin), which gives feces its characteristic color.

**Figure 19.5 Formation and destruction of red blood cells, and the recycling of hemoglobin components.** RBCs circulate for about 120 days after leaving red bone marrow before they are phagocytized by macrophages. The rate of RBC formation by red bone marrow equals the rate of RBC destruction by macrophages.
Erythropoiesis: Production of RBCs

Erythropoiesis (e-rith’-ró-poy-É-sis), the production of RBCs, starts in the red bone marrow with a precursor cell called a proerythroblast (see Figure 19.3). The proerythroblast divides several times, producing cells that begin to synthesize hemoglobin. Ultimately, a cell near the end of the development sequence ejects its nucleus and becomes a reticulocyte (re-TIK-ū-ló-sit). Loss of the nucleus causes the center of the cell to indent, producing the red blood cell’s distinctive biconcave shape. Reticulocytes retain some mitochondria, ribosomes, and endoplasmic reticulum. They pass from red bone marrow into the bloodstream by squeezing between the endothelial cells of blood capillaries. Reticulocytes develop into mature red blood cells within 1 to 2 days after their release from red bone marrow.

Normally, erythropoiesis and red blood cell destruction proceed at roughly the same pace. If the oxygen-carrying capacity of the blood falls because erythropoiesis is not keeping up with RBC destruction, a negative feedback system steps up RBC production (Figure 19.6). The controlled condition is the amount of oxygen delivered to body tissues. Cellular oxygen deficiency, called hypoxia (hi-POKS-ē-a), may occur if too little oxygen enters the blood. For example, the lower oxygen content of air at high altitudes reduces the amount of oxygen in the blood. Oxygen delivery may also fall due to anemia, which has many causes: Lack of iron, lack of certain amino acids, and lack of vitamin B<sub>12</sub> are but a few (see page 711). Circulatory problems that reduce blood flow to tissues may also reduce oxygen delivery. Whatever the cause, hypoxia stimulates the kidneys to step up the release of erythropoietin, which speeds the development of proerythroblasts into reticulocytes in the red bone marrow. As the number of circulating RBCs increases, more oxygen can be delivered to body tissues.

Premature newborns often exhibit anemia, due in part to inadequate production of erythropoietin. During the first weeks after birth, the liver, not the kidneys, produces most EPO.

Figure 19.6 Negative feedback regulation of erythropoiesis (red blood cell formation). Lower oxygen content of air at high altitudes, anemia, and circulatory problems may reduce oxygen delivery to body tissues.

Because the liver is less sensitive than the kidneys to hypoxia, newborns have a smaller EPO response to anemia than do adults. Because fetal hemoglobin (hemoglobin present at birth) carries up to 30% more oxygen, the loss of fetal hemoglobin, due to insufficient erythropoietin production, makes the anemia worse.
罹患贫血的人可能需要补充铁元素，因为铁元素是形成血红蛋白的重要成分。血红蛋白在血液中携带氧气，确保全身的氧气供应。研究表明，铁的补充可以显著提高血红蛋白水平，从而改善贫血症状。此外，血液中的白细胞——中性粒细胞、单核细胞、单核细胞——也扮演着重要的角色。它们参与了免疫系统的功能，帮助身体抵抗感染。白细胞的数量和活性在不同的健康状况下会有所变化，因此定期检查白细胞计数对于了解身体的健康状况至关重要。
lymphocytes has diagnostic significance in acute viral infections and in some immunodeficiency diseases. As noted earlier, there are three types of lymphocytes: T lymphocytes (T cells), B lymphocytes (B cells), and natural killer (NK) cells.

**Monocytes** (MON-ö-sëts) are 12–20 μm in diameter (Figure 19.7e). The nucleus of a monocyte is usually kidney shaped or horseshoe shaped, and the cytoplasm is blue-gray and has a foamy appearance. The color and appearance are due to very fine azurophilic granules (az-‘ô-řô-FIL-ik; azur- = blue; -philic = loving), which are lysosomes. The blood transports monocytes from the blood into the tissues, where they enlarge and differentiate into macrophages (= large eaters). Some become fixed macrophages, which means they reside in a particular tissue; examples are alveolar macrophages in the lungs, macrophages in the spleen, and stellate reticuloendothelial (Kupffer) cells in the liver. Others become wandering macrophages, which roam the tissues and gather at sites of infection or inflammation.

White blood cells and all other nucleated cells in the body have proteins, called major histocompatibility (MHC) antigens, protruding from their plasma membrane into the extracellular fluid. These “cell identity markers” are unique for each person (except identical twins). Although RBCs possess blood group antigens, they lack the MHC antigens.

### Functions of WBCs

In a healthy body, some WBCs, especially lymphocytes, can live for several months or years, but most live only a few days. During a period of infection, phagocytic WBCs may live only a few hours. WBCs are far less numerous than red blood cells; at about 5000–10,000 cells per μL of blood, they are outnumbered by RBCs by about 700:1. **Leukocytosis** (loo'-kô-së-TÔ-sës), an increase in the number of WBCs above 10,000/μL, is a normal, protective response to stresses such as invading microbes, strenuous exercise, anesthesia, and surgery. An abnormally low level of white blood cells (below 5000/μL) is termed leukopenia (loo'-kô-PÊ-në-a). It is never beneficial and may be caused by radiation, shock, and certain chemotherapeutic agents.

The skin and mucous membranes of the body are continuously exposed to microbes and their toxins. Some of these microbes can invade deeper tissues to cause disease. Once pathogens enter the body, the general function of white blood cells is to combat them by phagocytosis or immune responses. To accomplish these tasks, many WBCs leave the bloodstream and collect at sites of pathogen invasion or inflammation. Once granular leukocytes and monocytes leave the bloodstream to fight injury or infection, they never return to it. Lymphocytes, on the other hand, continually recirculate—from blood to interstitial spaces of tissues to lymphatic fluid and back to blood. Only 2% of the total lymphocyte population is circulating in the blood at any given time; the rest are in lymphatic fluid and organs such as the skin, lungs, lymph nodes, and spleen.

WBCs leave the bloodstream by a process termed **emigration** (em'-i-GRA-shun; e- = out; migra- = wander), formerly called **diapedesis** (di'-a-PE-sës), in which they roll along the endothelium, stick to it, and then squeeze between endothelial cells (Figure 19.8). The precise signals that stimulate emigration through a particular blood vessel vary for the different types of WBCs. Molecules known as **adhesion molecules** help WBCs stick to the endothelium. For example, endothelial cells display adhesion molecules called **selectins** in response to nearby injury and inflammation. Selectins stick to carbohydrates on the surface of neutrophils, causing them to slow down and roll along the endothelial surface. On the neutrophil surface are other adhesion molecules called **integrins**, which tether neutrophils to the endothelium and assist their movement through the blood vessel wall and into the interstitial fluid of the injured tissue.

Neutrophils and macrophages are active in **phagocytosis**; they can ingest bacteria and dispose of dead matter (see Figure 3.13 on page 75). Several different chemicals released by microbes and inflamed tissues attract phagocytes, a phenomenon called **chemotaxis**. The substances that provide stimuli for chemotaxis include toxins produced by microbes; kinins, which are specialized products of damaged tissues; and some of the colony-stimulating factors (CSFs). The CSFs also enhance the phagocytic activity of neutrophils and macrophages.

Among WBCs, neutrophils respond most quickly to tissue destruction by bacteria. After engulfling a pathogen during phagocytosis, a neutrophil releases potent enzymes and toxic molecules that kill and destroy the bacteria. If the neutrophil fails to destroy the pathogen, it may cause a local area of inflammation, which is manifested as redness, heat, swelling, and pain at the site. If the inflammation is severe, the neutrophil may undergo programmed cell death, or **apoptosis**. Apoptosis is a normal process that helps the body rid itself of damaged or unnecessary cells.

### Figure 19.8 Emigration of white blood cells.

Adhesion molecules (selectins and integrins) assist the emigration of WBCs from the bloodstream into interstitial fluid.

? In what way is the “traffic pattern” of lymphocytes in the body different from that of other WBCs?
cytosis, a neutrophil unleashes several chemicals to destroy the pathogen. These chemicals include the enzyme lysozyme, which destroys certain bacteria, and strong oxidants, such as the superoxide anion (O$_2^-$), hydrogen peroxide (H$_2$O$_2$), and the hypochlorite anion (OCl$^-$), which is similar to household bleach. Neutrophils also contain defensins, proteins that exhibit a broad range of antibiotic activity against bacteria and fungi. Within a neutrophil, vesicles containing defensins merge with phagosomes containing microbes. Defensins form peptide “spears” that poke holes in microbe membranes; the resulting loss of cellular contents kills the invader.

Monocytes take longer to reach a site of infection than neutrophils, but they arrive in larger numbers and destroy more microbes. Upon their arrival monocytes enlarge and differentiate into wandering macrophages, which clean up cellular debris and microbes by phagocytosis after an infection.

At sites of inflammation, basophils leave capillaries, enter tissues, and release granules that contain heparin, histamine, and serotonin. These substances intensify the inflammatory reaction and are involved in hypersensitivity (allergic) reactions. Basophils are similar in function to mast cells, connective tissue cells that originate from pluripotent stem cells in red bone marrow. Like basophils, mast cells release substances involved in inflammation, including heparin, histamine, and proteases. Mast cells are widely dispersed in the body, particularly in connective tissues of the skin and mucous membranes of the respiratory and gastrointestinal tracts.

Eosinophils leave the capillaries and enter tissue fluid. They are believed to release enzymes, such as histaminase, that combat the effects of histamine and other substances involved in inflammation during allergic reactions. Eosinophils also phagocyte antigen–antibody complexes and are effective against certain parasitic worms. A high eosinophil count often indicates an allergic condition or a parasitic infection.

Lymphocytes are the major soldiers in immune system battles (described in detail in Chapter 22). Most lymphocytes continually move among lymphoid tissues, lymph, and blood, spending only a few hours at a time in blood. Thus, only a small proportion of the total lymphocytes are present in the blood at any given time. Three main types of lymphocytes are B cells, T cells, and natural killer (NK) cells. B cells are particularly effective in destroying bacteria and inactivating their toxins. T cells attack viruses, fungi, transplanted cells, cancer cells, and some bacteria, and are responsible for transfusion reactions, allergies, and the rejection of transplanted organs. Immune responses carried out by both B cells and T cells help combat infection and provide protection against some diseases. Natural killer cells attack a wide variety of infectious microbes and certain spontaneously arising tumor cells.

As you have already learned, an increase in the number of circulating WBCs usually indicates inflammation or infection. A physician may order a differential white blood cell count, a count of each of the five types of white blood cells, to detect infection or inflammation, determine the effects of possible poisoning by chemicals or drugs, monitor blood disorders (for example, leukemia) and the effects of chemotherapy, or detect allergic reactions and parasitic infections. Because each type of white blood cell plays a different role, determining the percentage of each type in the blood assists in diagnosing the condition. Table 19.2 lists the significance of both high and low WBC counts.

**CHECKPOINT**
12. What is the importance of emigration, chemotaxis, and phagocytosis in fighting bacterial invaders?
13. How are leukocytosis and leukopenia different?
14. What is a differential white blood cell count?
15. What functions do granular leukocytes, macrophages, B cells, T cells, and natural killer cells perform?

**PLATELETS**

**OBJECTIVE**
- Describe the structure, function, and origin of platelets.

Besides the immature cell types that develop into erythrocytes and leukocytes, hemopoietic stem cells also differentiate into cells that produce platelets. Under the influence of the hormone thrombopoietin, myeloid stem cells develop into megakaryocyte-colony-forming cells that in turn develop into precursor cells called megakaryoblasts (see Figure 19.3). Megakaryoblasts transform into megakaryocytes, huge cells that splinter into 2000 to 3000 fragments. Each fragment, enclosed by a piece of the plasma membrane, is a platelet (thrombocyte). Platelets break off from the megakaryocytes in red bone marrow and then enter the blood circulation. Between 150,000
and 400,000 platelets are present in each μL of blood. Each is disc-shaped, 2–4 μm in diameter, and has many vesicles but no nucleus.

Platelets help stop blood loss from damaged blood vessels by forming a platelet plug. Their granules also contain chemicals that, once released, promote blood clotting. Platelets have a short life span, normally just 5 to 9 days. Aged and dead platelets are removed by fixed macrophages in the spleen and liver.

Table 19.3 summarizes the formed elements in blood.

†Some lymphocytes, called T and B memory cells, can live for many years once they are established.
CORD-BLOOD FROM BONE MARROW AND STEM CELL TRANSPLANTS

To decrease the chance of transplant rejection, kill the cancer cells and destroy the patient’s immune system in order to establish normal blood cell counts. In patients with cancer or certain genetic diseases, the defective red bone marrow is destroyed by high doses of chemotherapy and whole body radiation just before the transplant takes place. These treatments kill the cancer cells and destroy the patient’s immune system in order to decrease the chance of transplant rejection.

Healthy red bone marrow for transplanting may be supplied by a donor or by the patient when the underlying disease is inactive, as when leukemia is in remission. The red bone marrow from a donor is usually removed from the iliac crest of the hip bone under general anesthesia with a syringe and is then injected into the recipient’s vein, much like a blood transfusion. The injected marrow migrates to the recipient’s red bone marrow cavities, where the donor’s stem cells multiply. If all goes well, the recipient’s red bone marrow is replaced entirely by healthy, noncancerous cells.

Bone marrow transplants have been used to treat aplastic anemia, certain types of leukemia, severe combined immunodeficiency disease (SCID), Hodgkin’s disease, non-Hodgkin’s lymphoma, multiple myeloma, thalassemia, sickle-cell disease, breast cancer, ovarian cancer, testicular cancer, and hemolytic anemia. However, there are some drawbacks. Since the recipient’s white blood cells have been completely destroyed by chemotherapy and radiation, the patient is extremely vulnerable to infection. (It takes about 2–3 weeks for transplanted bone marrow to produce enough white blood cells to protect against infection.) In addition, transplanted red bone marrow may produce T cells that attack the recipient’s tissues, a reaction called graft-versus-host disease. Similarly, any of the recipient’s T cells that survived the chemotherapy and radiation can attack donor transplant cells. Another drawback is that patients must take immunosuppressive drugs for life. Because these drugs reduce the level of immune system activity, they increase the risk of infection. Immunosuppressive drugs also have side effects such as fever, muscle aches, headache, nausea, fatigue, depression, high blood pressure, and kidney and liver damage.

A more recent advance for obtaining stem cells involves a cord-blood transplant. The connection between the mother and embryo (and later the fetus) is the umbilical cord. Stem cells may be obtained from the umbilical cord shortly after birth. The stem cells are removed from the cord with a syringe and then frozen. Stem cells from the cord have several advantages over those obtained from red bone marrow:

1. They are easily collected following permission of the newborn’s parents.
2. They are more abundant than stem cells in red bone marrow.
3. They are less likely to cause graft-versus-host disease, so the match between donor and recipient does not have to be as close as in a bone marrow transplant. This provides a larger number of potential donors.
4. They are less likely to transmit infections.
5. They can be stored indefinitely in cord-blood banks.

CHECKPOINT

16. How do RBCs, WBCs, and platelets compare with respect to size, number per μL of blood, and life span?

STEM CELL TRANSPLANTS FROM BONE MARROW AND CORD-BLOOD

OBJECTIVES

- Explain the importance of bone marrow transplants and stem cell transplants.

A bone marrow transplant is the replacement of cancerous or abnormal red bone marrow with healthy red bone marrow in order to establish normal blood cell counts. In patients with cancer or certain genetic diseases, the defective red bone marrow is destroyed by high doses of chemotherapy and whole body radiation just before the transplant takes place. These treatments kill the cancer cells and destroy the patient’s immune system in order to decrease the chance of transplant rejection.

Healthy red bone marrow for transplanting may be supplied by a donor or by the patient when the underlying disease is inactive, as when leukemia is in remission. The red bone marrow from a donor is usually removed from the iliac crest of the hip bone under general anesthesia with a syringe and is then injected into the recipient’s vein, much like a blood transfusion. The injected marrow migrates to the recipient’s red bone marrow cavities, where the donor’s stem cells multiply. If all goes well, the recipient’s red bone marrow is replaced entirely by healthy, noncancerous cells.

Bone marrow transplants have been used to treat aplastic anemia, certain types of leukemia, severe combined immunodeficiency disease (SCID), Hodgkin’s disease, non-Hodgkin’s lymphoma, multiple myeloma, thalassemia, sickle-cell disease, breast cancer, ovarian cancer, testicular cancer, and hemolytic anemia. However, there are some drawbacks. Since the recipient’s white blood cells have been completely destroyed by chemotherapy and radiation, the patient is extremely vulnerable to infection. (It takes about 2–3 weeks for transplanted bone marrow to produce enough white blood cells to protect against infection.) In addition, transplanted red bone marrow may produce T cells that attack the recipient’s tissues, a reaction called graft-versus-host disease. Similarly, any of the recipient’s T cells that survived the chemotherapy and radiation can attack donor transplant cells. Another drawback is that patients must take immunosuppressive drugs for life. Because these drugs reduce the level of immune system activity, they increase the risk of infection. Immunosuppressive drugs also have side effects such as fever, muscle aches, headache, nausea, fatigue, depression, high blood pressure, and kidney and liver damage.

A more recent advance for obtaining stem cells involves a cord-blood transplant. The connection between the mother and embryo (and later the fetus) is the umbilical cord. Stem cells may be obtained from the umbilical cord shortly after birth. The stem cells are removed from the cord with a syringe and then frozen. Stem cells from the cord have several advantages over those obtained from red bone marrow:

1. They are easily collected following permission of the newborn’s parents.
2. They are more abundant than stem cells in red bone marrow.
3. They are less likely to cause graft-versus-host disease, so the match between donor and recipient does not have to be as close as in a bone marrow transplant. This provides a larger number of potential donors.
4. They are less likely to transmit infections.
5. They can be stored indefinitely in cord-blood banks.

CHECKPOINT

17. How are cord-blood transplants and bone marrow transplants similar? How do they differ?

HEMOSTASIS

OBJECTIVES

- Describe the three mechanisms that contribute to hemostasis.
- Identify the stages of blood clotting and explain the various factors that promote and inhibit blood clotting.

Hemostasis (hē-mō-STĀ-sis), not to be confused with the very similar term homeostasis, is a sequence of responses that stops bleeding. When blood vessels are damaged or ruptured, the hemostatic response must be quick, localized to the region of damage, and carefully controlled in order to be effective. Three mechanisms reduce blood loss: (1) vascular spasm, (2) platelet plug formation, and (3) blood clotting (coagulation). When successful, hemostasis prevents hemorrhage (HEM-o-rij; -rhage = burst forth), the loss of a large amount of blood from the vessels. Hemostatic mechanisms can prevent hemorrhage from smaller blood vessels, but extensive hemorrhage from larger vessels usually requires medical intervention.

Vascular Spasm

When arteries or arterioles are damaged, the circularly arranged smooth muscle in their walls contracts immediately, a reaction called vascular spasm. This reduces blood loss for several minutes to several hours, during which time the other hemostatic mechanisms go into operation. The spasm is probably caused by damage to the smooth muscle, by substances released from activated platelets, and by reflexes initiated by pain receptors.

Platelet Plug Formation

Considering their small size, platelets store an impressive array of chemicals. Within many vesicles are clotting factors, ADP, ATP, Ca²⁺, and serotonin. Also present are enzymes that produce thromboxane A₂, a prostaglandin; fibrin-stabilizing factor, which helps to strengthen a blood clot; lysosomes; some mitochondria; membrane systems that take up and store...
calcium and provide channels for release of the contents of granules; and glycogen. Also within platelets is platelet-derived growth factor (PDGF), a hormone that can cause proliferation of vascular endothelial cells, vascular smooth muscle fibers, and fibroblasts to help repair damaged blood vessel walls.

Platelet plug formation occurs as follows (Figure 19.9):

1. Initially, platelets contact and stick to parts of a damaged blood vessel, such as collagen fibers of the connective tissue underlying the damaged endothelial cells. This process is called platelet adhesion.
2. Due to adhesion, the platelets become activated, and their characteristics change dramatically. They extend many projections that enable them to contact and interact with one another, and they begin to liberate the contents of their vesicles. This phase is called the platelet release reaction. Liberated ADP and thromboxane A2 play a major role by activating nearby platelets. Serotonin and thromboxane A2 function as vasoconstrictors, causing and sustaining contraction of vascular smooth muscle, which decreases blood flow through the injured vessel.
3. The release of ADP makes other platelets in the area sticky, and the stickiness of the newly recruited and activated platelets causes them to adhere to the originally activated platelets. This gathering of platelets is called platelet aggregation. Eventually, the accumulation and attachment of large numbers of platelets form a mass called a platelet plug.

A platelet plug is very effective in preventing blood loss in a small vessel. Although initially the platelet plug is loose, it becomes quite tight when reinforced by fibrin threads formed during clotting (see Figure 19.10). A platelet plug can stop blood loss completely if the hole in a blood vessel is not too large.

### Blood Clotting

Normally, blood remains in its liquid form as long as it stays within its vessels. If it is drawn from the body, however, it thickens and forms a gel. Eventually, the gel separates from the liquid. The straw-colored liquid, called serum, is simply blood plasma minus the clotting proteins. The gel is called a clot. It consists of a network of insoluble protein fibers called fibrin in which the formed elements of blood are trapped (Figure 19.10).

The process of gel formation, called clotting or coagulation, is a series of chemical reactions that culminates in formation of fibrin threads. If blood clots too easily, the result can be thrombosis—clotting in an undamaged blood vessel. If the blood takes too long to clot, hemorrhage can occur.

Clotting involves several substances known as clotting (coagulation) factors. These factors include calcium ions (Ca²⁺), several inactive enzymes that are synthesized by hepatocytes (liver cells) and released into the bloodstream, and various molecules associated with platelets or released by damaged tissues. Most clotting factors are identified by Roman numerals that indicate the order of their discovery (not necessarily the order of their participation in the clotting process).

Clotting is a complex cascade of enzymatic reactions in which each clotting factor activates many molecules of the next one in a fixed sequence. Finally, a large quantity of product (the insoluble protein fibrin) is formed. Clotting can be divided into three stages (Figure 19.11):

1. Platelet adhesion
2. Platelet release reaction
3. Platelet aggregation

Along with platelet plug formation, which two mechanisms contribute to hemostasis?
Two pathways, called the extrinsic pathway (Figure 19.11a) and the intrinsic pathway (Figure 19.11b), which will be described shortly, lead to the formation of prothrombinase. Once prothrombinase is formed, the steps involved in the next two stages of clotting are the same for both the extrinsic and intrinsic pathways, and together these two stages are referred to as the common pathway.

Prothrombinase converts prothrombin (a plasma protein formed by the liver) into the enzyme thrombin.

Thrombin converts soluble fibrinogen (another plasma protein formed by the liver) into insoluble fibrin. Fibrin forms the threads of the clot.

Figure 19.10 Blood clot formation. Notice the platelet and red blood cells entrapped in fibrin threads.

A blood clot is a gel that contains formed elements of the blood entangled in fibrin threads.

What is serum?

What is the outcome of the first stage of blood clotting?
The Extrinsic Pathway
The extrinsic pathway of blood clotting has fewer steps than the intrinsic pathway and occurs rapidly—within a matter of seconds if trauma is severe. It is so named because a tissue protein called tissue factor (TF), also known as thromboplastin, leaks into the blood from cells outside (extrinsic to) blood vessels and initiates the formation of prothrombinase. TF is a complex mixture of lipoproteins and phospholipids released from the surfaces of damaged cells. In the presence of Ca$^{2+}$, TF begins a sequence of reactions that ultimately activates clotting factor X (Figure 19.11a). Once factor X is activated, it combines with factor V in the presence of Ca$^{2+}$ to form the active enzyme prothrombinase, completing the extrinsic pathway.

The Intrinsic Pathway
The intrinsic pathway of blood clotting is more complex than the extrinsic pathway, and it occurs more slowly, usually requiring several minutes. The intrinsic pathway is so named because its activators are either in direct contact with blood or contained within (intrinsic to) the blood; outside tissue damage is not needed. If endothelial cells become roughened or damaged, blood can come in contact with collagen fibers in the connective tissue around the endothelium of the blood vessel. In addition, trauma to endothelial cells causes damage to platelets, resulting in the release of phospholipids by the platelets. Contact with collagen fibers (or with the glass sides of a blood collection tube) activates clotting factor XII (Figure 19.11b), which begins a sequence of reactions that eventually activates clotting factor X. Platelet phospholipids and Ca$^{2+}$ can also participate in the activation of factor X. Once factor X is activated, it combines with factor V to form the active enzyme prothrombinase (just as occurs in the extrinsic pathway), completing the intrinsic pathway.

The Common Pathway
The formation of prothrombinase marks the beginning of the common pathway. In the second stage of blood clotting (Figure 19.11c), prothrombinase and Ca$^{2+}$ catalyze the conversion of prothrombin to thrombin. In the third stage, thrombin, in the presence of Ca$^{2+}$, converts fibrinogen, which is soluble, to loose fibrin threads, which are insoluble. Thrombin also activates factor XIII (fibrin stabilizing factor), which strengthens and stabilizes the fibrin threads into a sturdy clot. Plasma contains some factor XIII, which is also released by platelets trapped in the clot.

Thrombin has two positive feedback effects. In the first positive feedback loop, which involves factor V, it accelerates the formation of prothrombinase. Prothrombinase in turn accelerates the production of more thrombin, and so on. In the second positive feedback loop, thrombin activates platelets, which reinforces their aggregation and the release of platelet phospholipids.

Clot Retraction
Once a clot is formed, it plugs the ruptured area of the blood vessel and thus stops blood loss. Clot retraction is the consolidation or tightening of the fibrin clot. The fibrin threads attached to the damaged surfaces of the blood vessel gradually contract as platelets pull on them. As the clot retracts, it pulls the edges of the damaged vessel closer together, decreasing the risk of further damage. During retraction, some serum can escape between the fibrin threads, but the formed elements in blood cannot. Normal retraction depends on an adequate number of platelets in the clot, which release factor XIII and other factors, thereby strengthening and stabilizing the clot. Permanent repair of the blood vessel can then take place. In time, fibroblasts form connective tissue in the ruptured area, and new endothelial cells repair the vessel lining.

Role of Vitamin K in Clotting
Normal clotting depends on adequate levels of vitamin K in the body. Although vitamin K is not involved in actual clot formation, it is required for the synthesis of four clotting factors. Normally produced by bacteria that inhabit the large intestine, vitamin K is a fat-soluble vitamin that can be absorbed through the lining of the intestine and into the blood if absorption of lipids is normal. People suffering from disorders that slow absorption of lipids (for example, inadequate release of bile into the small intestine) often experience uncontrolled bleeding as a consequence of vitamin K deficiency.

The various clotting factors, their sources, and the pathways of activation are summarized in Table 19.4.

Hemostatic Control Mechanisms
Many times a day little clots start to form, often at a site of minor roughness or at a developing atherosclerotic plaque inside a blood vessel. Because blood clotting involves amplification and positive feedback cycles, a clot has a tendency to enlarge, creating the potential for impairment of blood flow through undamaged vessels. The fibrinolytic system (fi-bri-nöl-Í-tik) dissolves small, inappropriate clots; it also dissolves clots at a site of damage once the damage is repaired. Dissolution of a clot is called fibrinolysis (fi-bri-NOL-Í-sis). When a clot is formed, an inactive plasma enzyme called plasminogen is incorporated into the clot. Both body tissues and blood contain substances that can activate plasminogen to plasmin (fibri-nól-Í-sin), an active plasma enzyme. Among these substances are thrombin, activated factor XII, and tissue plasminogen activator (t-PA), which is synthesized in endothelial cells of most tissues and liberated into the blood. Once plasmin is formed, it can dissolve the clot by digesting fibrin threads and inactivating substances such as fibrinogen, prothrombin, and factors V and XII.

Even though thrombin has a positive feedback effect on blood clotting, clot formation normally remains localized at the site of damage. A clot does not extend beyond a wound site into the general circulation, in part because fibrin absorbs thrombin into the clot. Another reason for localized clot formation is that because of the dispersal of some of the clotting factors by the blood, their concentrations are not high enough to bring about widespread clotting.

Several other mechanisms also control blood clotting. For example, endothelial cells and white blood cells produce a
prostaglandin called prostacyclin (pros-ta-SI-klin) that opposes the actions of thromboxane A2. Prostacyclin is a powerful inhibitor of platelet adhesion and release.

In addition, substances that delay, suppress, or prevent blood clotting, called anticoagulants, are present in blood. These include antithrombin, which blocks the action of several factors, including XII, X, and II (prothrombin). Heparin, an anticoagulant that is produced by mast cells and basophils, combines with antithrombin and increases its effectiveness in blocking thrombin. Another anticoagulant, activated protein C (APC), inactivates the two major clotting factors not blocked by antithrombin and enhances activity of plasminogen activators. Babies that lack the ability to produce APC due to a genetic mutation usually die of blood clots in infancy.

*There is no factor VI. Prothrombinase (prothrombin activator) is a combination of activated factors V and X.

Intravascular Clotting

Despite the anticoagulating and fibrinolytic mechanisms, blood clots sometimes form within the cardiovascular system. Such clots may be initiated by roughened endothelial surfaces of a blood vessel resulting from atherosclerosis, trauma, or infection. These conditions induce adhesion of platelets. Intravascular clots may also form when blood flows too slowly (stasis), allowing clotting factors to accumulate locally in high enough concentrations to initiate coagulation. Clotting in an unbroken blood vessel (usually a vein) is called thrombosis (thromb-O-sis; thromb- = clot; -osis = a condition of). The clot itself, called a thrombus, may dissolve spontaneously. If it remains intact, however, the thrombus may become dislodged and be swept away in the blood. A blood clot, bubble of air, fat from broken bones, or a piece of debris transported by the bloodstream is called an embolus (embol- = in; bolus = a mass). An embolus that breaks away from an arterial wall may lodge in a smaller-diameter artery downstream and block blood flow to a vital organ. When an embolus lodges in the lungs, the condition is called pulmonary embolism.

**CLINICAL CONNECTION | Anticoagulants**

Patients who are at increased risk of forming blood clots may receive anticoagulants. Examples are heparin or warfarin. Heparin is often administered during hemodialysis and open-heart surgery. Warfarin (Coumadin®) acts as an antagonist to vitamin K and thus blocks synthesis of four clotting factors. Warfarin is slower acting than heparin. To prevent clotting in donated blood, blood banks and laboratories often add substances that remove Ca²⁺; examples are EDTA (ethylene diamine tetraacetic acid) and CPD (citrate phosphate dextrose). •

**CLINICAL CONNECTION | Aspirin and Thrombolytic Agents**

In patients with heart and blood vessel disease, the events of hemostasis may occur even without external injury to a blood vessel. At low doses, aspirin inhibits vasoconstriction and platelet aggregation by blocking synthesis of thromboxane A2. It also reduces the chance of thrombus formation. Due to these effects, aspirin reduces the risk of transient ischemic attacks (TIA), strokes, myocardial infarction, and blockage of peripheral arteries.

Thrombolytic agents are chemical substances that are injected into the body to dissolve blood clots that have already formed to restore circulation. They either directly or indirectly activate plasminogen. The first thrombolytic agent, approved in 1982 for dissolving clots in the coronary arteries of the heart, was streptokinase, which is produced by streptococcal bacteria. A genetically engineered version of human tissue plasminogen activator (t-PA) is now used to treat victims of both heart attacks and brain attacks (strokes) that are caused by blood clots. •
Blood plasma usually contains antibodies called agglutinins (a-gloo-ti-nins) that react with the A or B antigens if the two are mixed. These are the anti-A antibody, which reacts with antigen A, and the anti-B antibody, which reacts with antigen B. The antibodies present in each of the four blood types are shown in Figure 19.12. You do not have antibodies that react with the antigens of your own RBCs, but you do have antibodies for any antigens that your RBCs lack. For example, if your blood type is B, you have B antigens on your red blood cells, and you have anti-A antibodies in your blood plasma. Although agglutinins start to appear in the blood within a few months after birth, the reason for their presence is not clear. Perhaps they are formed in response to bacteria that normally inhabit the gastrointestinal tract. Because the antibodies are large IgM-type antibodies (see Table 22.3 on page 860) that do not cross the placenta, ABO incompatibility between a mother and her fetus rarely causes problems.

Transfusions

Despite the differences in RBC antigens reflected in the blood group systems, blood is the most easily shared of human tissues, saving many thousands of lives every year through transfusions. A transfusion (trans-FÜ-shun) is the transfer of whole blood or blood components (red blood cells only or blood plasma only) into the bloodstream or directly into the red bone marrow. A transfusion is most often given to alleviate anemia, to increase blood volume (for example, after a severe hemorrhage), or to improve immunity. However, the normal components of one person’s RBC plasma membrane can trigger damaging antigen–antibody responses in a transfusion recipient. In an incompatible blood transfusion, antibodies in the recipient’s plasma bind to the antigens on the donated RBCs, which causes agglutination (a-gloo-ti-NÄ-shun), or clumping, of the RBCs. Agglutination is an antigen–antibody response in which RBCs become cross-linked to one another. (Note that agglutination is not the same as blood clotting.) When these antigen–antibody complexes form, they activate plasma proteins of the complement family (described on page 860). In essence, complement molecules make the plasma membrane of the donated RBCs leaky, causing hemolysis (rupture) of the RBCs and the release of hemoglobin into the blood plasma. The liberated hemoglobin may cause kidney damage by clogging the filtration membranes. Although quite rare, it is possible for the viruses that cause AIDS and hepatitis B and C to be transmitted through transfusion of contaminated blood products.

Consider what happens if a person with type A blood receives a transfusion of type B blood. The recipient’s blood (type A) contains A antigens on the red blood cells and anti-B antibodies in the plasma. The donor’s blood (type B) contains B antigens and anti-A antibodies. In this situation, two things can happen. First, the anti-B antibodies in the recipient’s plasma can bind to the B antigens on the donor’s erythrocytes, causing agglutination and hemolysis of the red blood cells. Second, the anti-A antibodies in the donor’s plasma can bind to the A antigens on
the recipient’s red blood cells, a less serious reaction because the donor’s anti-A antibodies become so diluted in the recipient’s plasma that they do not cause significant agglutination and hemolysis of the recipient’s RBCs.

Table 19.6 summarizes the interactions of the four blood types of the ABO system.

People with type AB blood do not have anti-A or anti-B antibodies in their blood plasma. They are sometimes called universal recipients because theoretically they can receive blood from donors of all four blood types. They have no antibodies to attack antigens on donated RBCs (Table 19.6). People with type O blood have neither A nor B antigens on their RBCs and are sometimes called universal donors because theoretically they can donate blood to all four ABO blood types. Type O persons requiring blood may receive only type O blood (Table 19.6). In practice, use of the terms universal recipient and universal donor is misleading and dangerous. Blood contains antigens and antibodies other than those associated with the ABO system that can cause transfusion problems. Thus, blood should be carefully cross-matched or screened before transfusion. In about 80% of the population, soluble antigens of the ABO type appear in saliva and other body fluids, in which case blood type can be identified from a sample of saliva.

Rh Blood Group

The Rh blood group is so named because the antigen was discovered in the blood of the Rhesus monkey. The alleles of three genes may code for the Rh antigen. People whose RBCs have Rh antigens are designated Rh⁺ (Rh positive); those who lack Rh antigens are designated Rh⁻ (Rh negative). Table 19.5 shows the incidence of Rh⁺ and Rh⁻ in various populations. Normally, blood plasma does not contain anti-Rh antibodies. If an Rh⁻ person receives an Rh⁺ blood transfusion, however, the immune system starts to make anti-Rh antibodies that will remain in the blood. If a second transfusion of Rh⁺ blood is given later, the previously formed anti-Rh antibodies will cause agglutination and hemolysis of the RBCs in the donated blood, and a severe reaction may occur.
Typing and Cross-Matching Blood for Transfusion

To avoid blood-type mismatches, laboratory technicians type the patient’s blood and then either cross-match it to potential donor blood or screen it for the presence of antibodies. In the procedure for ABO blood typing, single drops of blood are mixed with different antisera, solutions that contain antibodies (Figure 19.14). One drop of blood is mixed with anti-A serum, which contains anti-A antibodies that will agglutinate red blood cells that possess A antigens. Another drop is mixed with anti-B serum, which contains anti-B antibodies that will agglutinate red blood cells that possess B antigens. If the red blood cells agglutinate with anti-A serum but not with anti-B serum, the blood type is A. If the cells agglutinate with anti-B serum but not with anti-A serum, the blood type is B. If they agglutinate with both anti-A and anti-B sera, the blood type is AB. If neither serum causes agglutination, the blood type is O.

Figure 19.14 ABO blood typing.

In the procedure for ABO blood typing, blood is mixed with anti-A serum and anti-B serum.

Figure 19.13 Development of hemolytic disease of the newborn (HDN). (a) At birth, a small quantity of fetal blood usually leaks across the placenta into the maternal bloodstream. A problem can arise when the mother is Rh− and the baby is Rh+, having inherited an allele for one of the Rh antigens from the father. (b) Upon exposure to Rh antigen, the mother’s immune system responds by making anti-Rh antibodies. (c) During a subsequent pregnancy, the maternal antibodies cross the placenta into the fetal blood. If the second fetus is Rh+, the ensuing antigen–antibody reaction causes agglutination and hemolysis of fetal RBCs. The result is HDN.

Why is the firstborn baby unlikely to have HDN?

What is agglutination?
nate only when mixed with anti-A serum, the blood is type A. If the red blood cells agglutinate only when mixed with anti-B serum, the blood is type B. The blood is type AB if both drops agglutinate; if neither drop agglutinates, the blood is type O.

In the procedure for determining Rh factor, a drop of blood is mixed with antiseraum containing antibodies that will agglutinate RBCs displaying Rh antigens. If the blood agglutinates, it is Rh⁺; no agglutination indicates Rh⁻.

Once the patient’s blood type is known, donor blood of the same ABO and Rh type is selected. In a cross-match, the possible donor RBCs are mixed with the recipient’s serum. If agglutination does not occur, the recipient does not have antibodies that will attack the donor RBCs. Alternatively, the recipient’s serum can be screened against a test panel of RBCs having antigens known to cause blood transfusion reactions to detect any antibodies that may be present.

**CHECKPOINT**
23. What precautions must be taken before giving a blood transfusion?
24. What is hemolysis, and how can it occur after a mismatched blood transfusion?
25. Explain the conditions that may cause hemolytic disease of the newborn.

---

**DISORDERS: HOMEOSTATIC IMBALANCES**

**Anemia**

Anemia is a condition in which the oxygen-carrying capacity of blood is reduced. All of the many types of anemia are characterized by reduced numbers of RBCs or a decreased amount of hemoglobin in the blood. The person feels fatigued and is intolerant of cold, both of which are related to lack of oxygen needed for ATP and heat production. Also, the skin appears pale, due to the low content of red-colored hemoglobin circulating in skin blood vessels. Among the most important causes and types of anemia are the following:

- **Inadequate absorption of iron,** **excessive loss of iron,** **increased iron requirement,** or **insufficient intake of iron** causes **iron-deficiency anemia,** the most common type of anemia. Women are at greater risk for iron-deficiency anemia due to menstrual blood losses and increased iron demands of the growing fetus during pregnancy. Gastrointestinal losses, such as those that occur with malignancy or ulceration, also contribute to this type of anemia.
- **Inadequate intake of vitamin B₁₂** or folic acid causes **megaloblastic anemia** in which red bone marrow produces large, abnormal red blood cells (megaloblasts). It may also be caused by drugs that alter gastric secretion or are used to treat cancer.
- **Insufficient hemopoiesis** resulting from an inability of the stomach to produce intrinsic factor, which is needed for absorption of vitamin B₁₂ in the small intestine, causes **pernicious anemia.**
- **Excessive loss of RBCs** through bleeding resulting from large wounds, stomach ulcers, or especially heavy menstruation leads to **hemorrhagic anemia.**
- **RBC plasma membranes rupture prematurely** in **hemolytic anemia.** The released hemoglobin pours into the plasma and may damage the filtering units (glomeruli) in the kidneys. The condition may result from inherited defects such as abnormal red blood cell enzymes, or from outside agents such as parasites, toxins, or antibodies from incompatible transfused blood.
- **Deficient synthesis of hemoglobin** occurs in **thalassemia** (thal-axis-mé-a), a group of hereditary hemolytic anemias. The RBCs are small (microcytic), pale (hypochromic), and short-lived. Thalassemia occurs primarily in populations from countries bordering the Mediterranean Sea.
- **Destruction of red bone marrow** results in **aplastic anemia.** It is caused by toxins, gamma radiation, and certain medications that inhibit enzymes needed for hemopoiesis.

---

**Sickle-Cell Disease**

The RBCs of a person with **sickle-cell disease (SCD)** contain Hb-S, an abnormal kind of hemoglobin. When Hb-S gives up oxygen to the interstitial fluid, it forms long, stiff, rodlike structures that bend the erythrocyte into a sickle shape (Figure 19.15). The sickled cells rupture easily. Even though erythropoiesis is stimulated by the loss of the cells, it cannot keep pace with hemolysis. People with sickle-cell disease always have some degree of anemia and mild jaundice and may experience joint or bone pain, breathlessness, rapid heart rate, abdominal pain, fever, and fatigue as a result of tissue damage caused by prolonged recovery oxygen uptake (oxygen debt). Any activity that reduces the amount of oxygen in the blood, such as vigorous exercise, may produce a sickle-cell crisis (worsening of the anemia, pain in the abdomen and long bones of the limbs, fever, and shortness of breath).

Sickle-cell disease is inherited. People with two sickle-cell genes have severe anemia; those with only one defective gene have minor problems. Sickle-cell genes are found primarily among populations, or

---

**Figure 19.15** Red blood cells from a person with sickle-cell disease.

- The red blood cells of a person with sickle-cell disease contain an abnormal type of hemoglobin called Hb-S.

---

- What are some symptoms of sickle-cell disease?
of clotting in which bleeding may occur spontaneously or after only
hemophilia;
use is questionable.
has toxic effects on the bone marrow; thus, its safety for long-term
tation of the normal Hb-F gene, elevates the level of Hb-F, and reduces
bin (Hb-F), a slightly different form of hemoglobin that predominates
sickled cells, causing potassium ions to leak out. Low levels of potas-
to sickle also alters the permeability of the plasma membranes of
The term leukemia (loo-KÉ-mé-a; leuко- = white) refers to a group of
red bone marrow cancers in which abnormal white blood cells multi-
leukemia
nous or traumatic subcutaneous and intramuscular hemorrhaging,
nosebleeds, blood in the urine, and hemorrhages in joints that pro-
duce pain and tissue damage. Treatment involves transfusions of fresh
blood plasma or concentrates of the deficient clotting factor to relieve
the tendency to bleed. Another treatment is the drug desmopressin
(DDAVP), which can boost the levels of the clotting factors.

Leukemia
The term leukemia (loo-KÉ-mé-a; leuко- = white) refers to a group of
red bone marrow cancers in which abnormal white blood cells multi-
uncontrollably. The accumulation of the cancerous white blood cells
in red bone marrow interferes with the production of red blood
cells, white blood cells, and platelets. As a result the oxygen-carrying
capacity of the blood is reduced, an individual is more susceptible to
infection, and blood clotting is abnormal. In most leukemias, the can-
cerous white blood cells spread to the lymph nodes, liver, and spleen,
causing them to enlarge. All leukemias produce the usual symptoms
of anemia (fatigue, intolerance to cold, and pale skin). In addition,
weight loss, fever, night sweats, excessive bleeding, and recurrent
infections may occur.

In general, leukemias are classified as acute (symptoms develop
rapidly) and chronic (symptoms may take years to develop). Adults
may have either type, but children usually have the acute type.
The cause of most types of leukemia is unknown. However, certain
risk factors have been implicated. These include exposure to radiation
or chemotherapy for other cancers, genetics (some genetic disorders
such as Down syndrome), environmental factors (smoking and ben-
zene), and microbes such as the human T cell leukemia-lymphoma
virus-1 (HTLV-1) and the Epstein-Barr virus.

Treatment options include chemotherapy, radiation, stem cell trans-
plantation, interferon, antibodies, and blood transfusion.

MEDICAL TERMINOLOGY

Acute normovolemic hemodilution (nor-mó-vô-LÉ-mik hémô-di-LOO-
shun) Removal of blood immediately before surgery and its re-
placement with a cell-free solution to maintain sufficient blood vol-
ume for adequate circulation. At the end of surgery, once bleeding
has been controlled, the collected blood is returned to the body.

Autologous preoperative transfusion (aw-TOL-o-gus trans-FÜ-zhen; auto-
= self) Donating one’s own blood; can be done up to 6 weeks be-
fore elective surgery. Also called predonation. This procedure elimi-
nates the risk of incompatibility and blood-borne disease.

Blood bank A facility that collects and stores a supply of blood for
future use by the donor or others. Because blood banks have addi-
tional and diverse functions (immunohematology reference work,
continuing medical education, bone and tissue storage, and clinical
consultation), they are more appropriately referred to as centers of
transfusion medicine.

Cyanosis (si-a-NÔ-sis; cyano- = blue) Slightly bluish/dark-purple skin
discoloration, most easily seen in the nail beds and mucous mem-
branes, due to an increased quantity of reduced hemoglobin (he-
moglobin not combined with oxygen) in systemic blood.

Gamma globulin (GLOB-û-lin) Solution of immunoglobulins from blood
consisting of antibodies that react with specific pathogens, such as
viruses. It is prepared by injecting the specific virus into animals,
removing blood from the animals after antibodies have accumu-
lated, isolating the antibodies, and injecting them into a human to
provide short-term immunity.

Hemochromatosis (hémô-kro-mat-Ô-sis; chroma = color) Disorder of
iron metabolism characterized by excessive absorption of ingested
iron and excess deposits of iron in tissues (especially the liver,
heart, pituitary gland, gonads, and pancreas) that result in bronze
discoloration of the skin, cirrhosis, diabetes mellitus, and bone
and joint abnormalities.

Hemorrhage (HEM-or-iж; rhegynai = bursting forth) Loss of a large
amount of blood; can be either internal (from blood vessels into
tissues) or external (from blood vessels directly to the surface of
the body).

Jaundice (jaund- = yellow) An abnormal yellowish discoloration of the
sclerae of the eyes, skin, and mucous membranes due to excess
bilirubin (yellow-orange pigment) in the blood. The three main
categories of jaundice are prehepatic jaundice, due to excess
production of bilirubin; hepatic jaundice, abnormal bilirubin
processing by the liver caused by congenital liver disease, cirrhosis
(scar tissue formation) of the liver, or hepatitis (liver inflammation);
and extrahepatic jaundice, due to blockage of bile drainage by
gallstones or cancer of the bowel or pancreas.

Phlebotomist (fle-BOT-o-mist; phlebo- = vein; -tom = cut) A technician
who specializes in withdrawing blood.

Septicemia (sep’ti-SÉ-mé-a; septic- = decay; -emia = condition of
blood) Toxins or disease-causing bacteria in the blood. Also called
“blood poisoning.”

Thrombocytopenia (throm’-bô-si-tô-PÉ-né-a; -penia = poverty) Very low
Venesection (ven-ē-sek-shun; ven- = vein) Opening of a vein for withdrawal of blood. Although phlebotomy (fle-boh-tome) is a synonym for venesection, in clinical practice phlebotomy refers to therapeutic bloodletting, such as the removal of some blood to lower its viscosity in a patient with polycythemia. Whole blood Blood containing all formed elements, plasma, and plasma solutes in natural concentrations.

### Study Outline

#### Introduction (p. 689)
1. The cardiovascular system consists of the blood, heart, and blood vessels.
2. Blood is a connective tissue composed of blood plasma (liquid portion) and formed elements (cells and cell fragments).

#### Functions and Properties of Blood (p. 690)
2. It helps regulate pH, body temperature, and water content of cells.
3. It provides protection through clotting and by combating toxins and microbes through certain phagocytic white blood cells or specialized blood plasma proteins.
4. Physical characteristics of blood include a viscosity greater than that of water; a temperature of 38°C (100.4°F); and a pH of 7.35–7.45.
5. Blood constitutes about 8% of body weight, and its volume is 4–6 liters in adults.
6. Blood is about 55% blood plasma and 45% formed elements.
7. The hematocrit is the percentage of total blood volume occupied by red blood cells.
8. Blood plasma consists of 91.5% water and 8.5% solutes. Principal solutes include proteins (albumins, globulins, fibrinogen), nutrients, vitamins, hormones, respiratory gases, electrolytes, and waste products.
9. The formed elements in blood include red blood cells (erythrocytes), white blood cells (leukocytes), and platelets.

#### Formation of Blood Cells (p. 693)
1. Hemopoiesis is the formation of blood cells from hemopoietic stem cells in red bone marrow.
2. Myeloid stem cells form RBCs, platelets, granulocytes, and monocytes. Lymphoid stem cells give rise to lymphocytes.
3. Several hemopoietic growth factors stimulate differentiation and proliferation of the various blood cells.

#### Red Blood Cells (p. 695)
1. Mature RBCs are biconcave discs that lack nuclei and contain hemoglobin.
2. The function of the hemoglobin in red blood cells is to transport oxygen and some carbon dioxide.
3. RBCs live about 120 days. A healthy male has about 5.4 million RBCs/µL of blood; a healthy female has about 4.8 million/µL.
4. After phagocytosis of aged RBCs by macrophages, hemoglobin is recycled.
5. RBC formation, called erythropoiesis, occurs in adult red bone marrow of certain bones. It is stimulated by hypoxia, which stimulates the release of erythropoietin by the kidneys.
6. A reticulocyte count is a diagnostic test that indicates the rate of erythropoiesis.

#### White Blood Cells (p. 699)
1. WBCs are nucleated cells. The two principal types are granulocytes (neutrophils, eosinophils, and basophils) and agranulocytes (lymphocytes and monocytes).
2. The general function of WBCs is to combat inflammation and infection. Neutrophils and macrophages (which develop from monocytes) do so through phagocytosis.
3. Eosinophils combat the effects of histamine in allergic reactions, phagocytize antigen–antibody complexes, and combat parasitic worms. Basophils liberate heparin, histamine, and serotonin in allergic reactions that intensify the inflammatory response.
4. B lymphocytes, in response to the presence of foreign substances called antigens, differentiate into plasma cells that produce antibodies. Antibodies attach to the antigens and render them harmless. This antigen–antibody response combats infection and provides immunity. T lymphocytes destroy foreign invaders directly. Natural killer cells attack infectious microbes and tumor cells.
5. Except for lymphocytes, which may live for years, WBCs usually live for only a few hours or a few days. Normal blood contains 5000–10,000 WBCs/µL.

#### Platelets (p. 701)
1. Platelets (thrombocytes) are disc-shaped cell fragments that splinter from megakaryocytes. Normal blood contains 150,000–400,000 platelets/µL.
2. Platelets help stop blood loss from damaged blood vessels by forming a platelet plug.

#### Stem Cell Transplants from Bone Marrow and Cord-Blood (p. 703)
1. Bone marrow transplants involve removal of red bone marrow as a source of stem cells from the iliac crest.
2. In a cord-blood transplant, stem cells from the placenta are removed from the umbilical cord.
3. Cord-blood transplants have several advantages over bone marrow transplants.

#### Hemostasis (p. 703)
1. Hemostasis refers to the stoppage of bleeding.
2. It involves vascular spasm, platelet plug formation, and blood clotting (coagulation).
3. In vascular spasm, the smooth muscle of a blood vessel wall contracts, which slows blood loss.
4. Platelet plug formation involves the aggregation of platelets to stop bleeding.
5. A clot is a network of insoluble protein fibers (fibrin) in which formed elements of blood are trapped.
6. The chemicals involved in clotting are known as clotting (coagulation) factors.
7. Blood clotting involves a cascade of reactions that may be divided into three stages: formation of prothrombinase, conversion of prothrombin into thrombin, and conversion of soluble fibrinogen into insoluble fibrin.
8. Clotting is initiated by the interplay of the extrinsic and intrinsic pathways of blood clotting.
9. Normal coagulation requires vitamin K and is followed by clot retraction (tightening of the clot) and ultimately fibrinolysis (dissolution of the clot).

**SELF-QUIZ QUESTIONS**

**Fill in the blanks in the following statements.**

1. Plasma minus its clotting proteins is termed _____.
2. _____ is the consolidation or tightening of the fibrin clot that helps to bring the edges of a damaged vessel closer together.

**Indicate whether the following statements are true or false.**

3. Hemoglobin functions in transporting both oxygen and carbon dioxide and in regulating blood pressure.
4. The most numerous white blood cells in a differential white blood cell count of a healthy individual are the neutrophils.

**Choose the one best answer to the following questions.**

5. Which of the following are not required for clot formation? (1) vitamin K, (2) calcium, (3) prostacyclin, (4) plasmin, (5) fibrinogen.
   (a) 1, 2, and 5 (b) 3, 4, and 5 (c) 4 and 5 (d) 1, 2, and 3 (e) 3 and 4

6. Place the steps involved in hemostasis in the correct order: (1) conversion of fibrinogen into fibrin, (2) conversion of prothrombin into thrombin, (3) adhesion and aggregation of platelets on damaged vessel, (4) prothrombinase formed by extrinsic or intrinsic pathway, (5) reduction of blood loss by initiation of a vascular spasm.
   (a) 5, 3, 4, 2, 1 (b) 5, 4, 3, 1, 2 (c) 3, 5, 4, 2, 1 (d) 5, 3, 2, 1, 4 (e) 3, 2, 4, 1

7. Which of the following statements explain why red blood cells (RBCs) are highly specialized for oxygen transport? (1) RBCs contain hemoglobin. (2) RBCs lack a nucleus. (3) RBCs have many mitochondria and thus generate ATP aerobically. (4) The biconcave shape of RBCs provides a large surface area for the inward and outward diffusion of gas molecules. (5) RBCs can carry up to four oxygen molecules for each hemoglobin molecule.
   (a) 1, 2, 3, and 5 (b) 1, 2, 4, and 5 (c) 2, 3, 4, and 5 (d) 1, 3, and 5 (e) 2, 4, and 5

8. Which of the following are true? (1) White blood cells leave the bloodstream by emigration. (2) Adhesion molecules help white blood cells stick to the endothelium, which aids emigration. (3) Neutrophils and macrophages are active in phagocytosis. (4) The attraction of phagocytes to microbes and inflamed tissue is termed chemotaxis. (5) Leukopenia is an increase in white blood cell count that occurs during infection.
   (a) 1, 2, 4, and 5 (b) 2, 3, 4, and 5 (c) 1, 2, 3, and 4 (d) 1, 3, and 5 (e) 1, 2, and 4

9. A person with type A Rh- blood can receive a blood transfusion from which of the following types? (1) A Rh+, (2) B Rh+, (3) AB Rh+, (4) O Rh-, (5) A Rh-.
   (a) 1 only (b) 3 only (c) 4 only (d) 4 and 5 (e) 1 and 5

10. A person with type B positive blood receives a transfusion of type AB positive blood. What will happen?
   (a) The recipient’s antibodies will react with the donor’s red blood cells.
   (b) The donor’s antigens will destroy the recipient’s antibodies.
   (c) The donor’s antibodies will react with and destroy all of the recipient’s red blood cells.
   (d) The recipient’s blood type will change from Rh+ to Rh-.
   (e) These blood types are compatible, and the transfusion will be accepted.

11. What happens to the iron (Fe$_3^+$) that is released during the breakdown of damaged red blood cells?
   (a) It is used to synthesize proteins.
   (b) It is transported to the liver where it becomes part of bile.
   (c) It is converted into urobinin and excreted in urine.
   (d) It attaches to transferrin and is transported to bone marrow for use in hemoglobin synthesis.
   (e) It is utilized by intestinal bacteria to convert bilirubin into urobilinogen.

12. Which of the following would not cause an increase in erythropoietin?
   (a) anemia (b) high altitude (c) hemorrhage (d) donating blood to a blood bank (e) polycythemia

10. Clotting in an unbroken blood vessel is called thrombosis. A thrombus that moves from its site of origin is called an embolus.

**Blood Groups and Blood Types (p. 708)**

1. ABO and Rh blood groups are genetically determined and based on antigen–antibody responses.
2. In the ABO blood group, the presence or absence of A and B antigens on the surface of RBCs determines blood type.
3. In the Rh system, individuals whose RBCs have Rh antigens are classified as Rh$^+$; those who lack the antigen are Rh$^-$.
4. Hemolytic disease of the newborn (HDN) can occur when an Rh$^-$ mother is pregnant with an Rh$^+$ fetus.
5. Before blood is transfused, a recipient’s blood is typed and then either cross-matched to potential donor blood or screened for the presence of antibodies.
13. Match the following:
- (a) contain hemoglobin and function in gas transport
- (b) cell fragments enclosed by a piece of the cell membrane of megakaryocytes; contain clotting factors
- (c) individual forms of progenitor cells; named on the basis of the mature elements in blood they will ultimately produce
- (d) white blood cell showing a kidney-shaped nucleus; capable of phagocytosis
- (e) monocytes that roam the tissues and gather at sites of infection or inflammation
- (f) occur as B cells, T cells, and natural killer cells
- (g) give rise to red blood cells, monocytes, neutrophils, eosinophils, basophils, and platelets
- (h) combat the effects of histamine and other mediators of inflammation in allergic reactions; also phagocytize antigen–antibody complexes
- (i) respond to tissue destruction by bacteria; release lysozyme, strong oxidants, and defensins
- (j) older neutrophils with several differently shaped nuclear lobes
- (k) released from the red bone marrow, they develop into mature red blood cells
- (l) give rise to lymphocytes
- (m) cells no longer capable of replenishing themselves; can only give rise to more specific formed elements of blood
- (n) hormone that stimulates formation of platelets
- (o) monocytes that leave the blood and reside in a particular tissue such as alveolar macrophages in the lungs
- (p) involved in inflammatory and allergic reactions; are involved in hypersensitivity reactions
- (q) stimulate white blood cell formation
- (r) cells that give rise to all the formed elements of blood; derived from mesenchyme
- (s) hormone that increases the numbers of red blood cell precursors

14. Match the following:
- (a) tissue protein that leaks into the blood from cells outside blood vessels and initiates the formation of prothrombinase
- (b) an anticoagulant
- (c) platelet hormone that stimulates repair of damaged vessel walls
- (d) its formation is initiated by either the extrinsic or intrinsic pathway or both; catalyzes the conversion of prothrombin to thrombin
- (e) glycoproteins and glycolipids on the surfaces of red blood cells that can act as antigens
- (f) forms the threads of a clot; produced from fibrinogen
- (g) can dissolve a clot by digesting fibrin threads
- (h) serves as the catalyst to form fibrin; formed from prothrombin

15. Match the following:
- (a) the percentage of total blood volume occupied by red blood cells
- (b) the percentage of each type of white blood cell
- (c) measures numbers of RBCs, WBCs, platelets per μ of blood; hematocrit; and differential WBC count
- (d) measures the rate of erythropoiesis
- (e) withdrawal of blood from a vein using a needle and collecting tube
- (f) withdrawal of a small amount of red bone marrow with a fine needle and syringe
- (g) removal of a core of red bone marrow with a large needle
1. Shilpa has recently been on broad spectrum antibiotics for a recurrent urinary bladder infection. While slicing vegetables, she cut herself and had difficulty stopping the bleeding. How could the antibiotics have played a role in her bleeding?

2. Mrs. Brown is in renal failure. Her recent blood tests indicated a hematocrit of 22. Why is her hematocrit low? What can she be given to raise her hematocrit?

3. Thomas has hepatitis, which is disrupting his liver functions. What kinds of symptoms would he be experiencing based on the role(s) of the liver related to blood?

19.1 Blood volume is about 8% of your body mass, roughly 5–6 liters in males and 4–5 liters in females. For instance, a 70-kg (150-lb.) person has a blood volume of 5.6 liters (70 kg \times 8\% \times 1 liter/kg).

19.2 Platelets are cell fragments.

19.3 Pluripotent stem cells develop from mesenchyme.

19.4 One hemoglobin molecule can transport a maximum of four O₂ molecules, one O₂ bound to each heme group.

19.5 Transferrin is a plasma protein that transports iron in the blood.

19.6 Once you moved to high altitude, your hematocrit would increase due to increased secretion of erythropoietin.

19.7 Neutrophils, eosinophils, and basophils are called granular leukocytes because all have cytoplasmic granules that are visible through a light microscope when stained.

19.8 Lymphocytes recirculate from blood to tissues and back to blood. After leaving the blood, other WBCs remain in the tissues until they die.

19.9 Along with platelet plug formation, vascular spasm and blood clotting contribute to hemostasis.

19.10 Serum is blood plasma minus the clotting proteins.

19.11 The outcome of the first stage of clotting is the formation of prothrombinase.

19.12 Type O blood usually contains both anti-A and anti-B antibodies.

19.13 Because the mother is most likely to start making anti-Rh antibodies after the first baby is already born, that baby suffers no damage.

19.14 Agglutination refers to clumping of red blood cells.

19.15 Some symptoms of sickle-cell disease are anemia, mild jaundice, joint pain, shortness of breath, rapid heart rate, abdominal pain, fever, and fatigue.
As you learned in the previous chapter, the cardiovascular system consists of the blood, the heart, and blood vessels. We also examined the composition and functions of blood, and in this chapter you will learn about the pump that circulates it throughout the body—the heart. Blood must be constantly pumped through the body’s blood vessels so that it can reach body cells and exchange materials with them. To accomplish this, the heart beats about 100,000 times every day, which adds up to 35 million beats in a year and about 2.5 billion times in an average lifetime. Even while you are sleeping, your heart pumps 30 times its own weight (5 L or 5.3 qt) each minute, which amounts to more than 14,000 liters (3600 gal) of blood in a day and 10 million liters (2.6 million gal) in a year. Because you don’t spend all your time sleeping, and your heart pumps more vigorously when you are active, the actual blood volume the heart pumps in a single day is even larger.

The scientific study of the normal heart and the diseases associated with it is known as cardiology (kar’-dē-OL-ō-jē; cardio- = heart; -logy = study of). This chapter explores the structure of the heart and the unique properties that permit it to pump for a lifetime without rest.
ANATOMY OF THE HEART

OBJECTIVES

- Describe the location of the heart.
- Describe the structure of the pericardium and the heart wall.
- Discuss the external and internal anatomy of the chambers of the heart.

Location of the Heart

For all its might, the heart is relatively small, roughly the same size (but not the same shape) as your closed fist. It is about 12 cm (5 in.) long, 9 cm (3.5 in.) wide at its broadest point, and 6 cm (2.5 in.) thick, with an average mass of 250 g (8 oz) in adult females and 300 g (10 oz) in adult males. The heart rests on the diaphragm, near the midline of the thoracic cavity. It lies in the mediastinum (me¯-de¯-a-STI¯-num), an anatomical region that extends from the sternum to the vertebral column, the first rib to the diaphragm, and between the lungs (Figure 20.1a). About two-thirds of the mass of the heart lies to the left of the body’s midline (Figure 20.1b). You can visualize the heart as a cone lying on its side. The pointed apex is formed by the tip of the left ventricle (a lower chamber of the heart) and rests on the diaphragm. It is directed anteriorly, inferiorly, and to the left. The base of the heart is its posterior surface. It is formed by the atria (upper chambers) of the heart, mostly the left atrium.

Figure 20.1 Position of the heart and associated structures in the mediastinum (dashed outline). (See Tortora, *A Photographic Atlas of the Human Body, Second Edition*, Figures 6.5 and 6.6.)

The heart is located in the mediastinum, with two-thirds of its mass to the left of the midline.

What is the mediastinum?
In addition to the apex and base, the heart has several distinct surfaces and borders (margins). The **anterior surface** is deep to the sternum and ribs. The **inferior surface** is the part of the heart between the apex and right border and rests mostly on the diaphragm (Figure 20.1b). The **right border** faces the right lung and extends from the inferior surface to the base. The **left border**, also called the **pulmonary border**, faces the left lung and extends from the base to the apex.

**Pericardium**

The membrane that surrounds and protects the heart is the **pericardium** (*peri-* = around). It confines the heart to its position in the mediastinum, while allowing sufficient freedom of movement for vigorous and rapid contraction. The pericardium consists of two main parts: (1) the fibrous pericardium and (2) the serous pericardium (Figure 20.2a). The superficial **fibrous pericardium** is composed of tough, inelastic, dense irregular connective tissue. It resembles a bag that rests on and attaches to the diaphragm; its open end is fused to the connective tissues of the blood vessels entering and leaving the heart. The fibrous pericardium prevents overstretching of the heart, provides protection, and anchors the heart in the mediastinum.

The deeper **serous pericardium** is a thinner, more delicate membrane that forms a double layer around the heart (Figure 20.2a). The outer **parietal layer** of the serous pericardium is fused to the fibrous pericardium. The inner **visceral layer** of the serous pericardium, also called the **epicardium** (*epi-* = on top of), is one of the layers of the heart wall and adheres tightly to the surface of the heart. Between the parietal and visceral layers of the serous pericardium is a thin film of lubricating serous fluid. This slippery secretion of the pericardial cells, known as **pericardial fluid**, reduces friction between the layers of the serous pericardium as the heart moves. The space that contains the few milliliters of pericardial fluid is called the **pericardial cavity**.

**Clinical Connection**

Because the heart lies between two rigid structures—the vertebral column and the sternum (Figure 20.1a)—external pressure on the chest (compression) can be used to force blood out of the heart and into the circulation. In cases in which the heart suddenly stops beating, **cardiopulmonary resuscitation (CPR)**—properly applied cardiac compressions, performed with artificial ventilation of the lungs via mouth-to-mouth respiration—saves lives. CPR keeps oxygenated blood circulating until the heart can be restarted.

In a 2007 Japanese study, researchers found that chest compressions alone are equally as effective as, if not better than, traditional CPR with lung ventilation. This is good news because it is easier for an emergency dispatcher to give instructions limited to chest compressions to frightened, nonmedical bystanders. As public fear of contracting contagious diseases such as hepatitis, HIV, and tuberculosis continues to rise, bystanders are much more likely to perform chest compressions alone than treatment involving mouth-to-mouth rescue breathing.

**Figure 20.2 Pericardium and heart wall.**

The pericardium is a triple-layered sac that surrounds and protects the heart.
The wall of the heart consists of three layers (Figure 20.2a): the

**Layers of the Heart Wall**

The wall of the heart consists of three layers (Figure 20.2a): the epicardium (external layer), the myocardium (middle layer), and the endocardium (inner layer). As noted earlier, the outermost epicardium, the thin, transparent outer layer of the heart wall, is also called the visceral layer of the serous pericardium. It is composed of mesothelium and delicate connective tissue that imparts a smooth, slippery texture to the outermost surface of the heart. The middle myocardium (myo- = muscle), which is cardiac muscle tissue, makes up about 95% of the heart and is responsible for its pumping action. Although it is striated like skeletal muscle, cardiac muscle is involuntary like smooth muscle. The cardiac muscle fibers swirl diagonally around the heart in bundles (Figure 20.2c). The innermost endocardium (endo- = within) is a thin layer of endothelium overlying a thin layer of connective tissue. It provides a smooth lining for the chambers of the heart and covers the valves of the heart. The endocardium is continuous with the endothelial lining of the large blood vessels attached to the heart, and it minimizes surface friction as blood passes through the heart and blood vessels.

**CHLINAL CONNECTION | Myocarditis and Endocarditis**

Myocarditis (mi-ô-kar-Di-tis) is an inflammation of the myocardium that usually occurs as a complication of a viral infection, rheumatic fever, or exposure to radiation or certain chemicals or medications. Myocarditis often has no symptoms. However, if they do occur, they may include fever, fatigue, vague chest pain, irregular or rapid heartbeat, joint pain, and breathlessness. Myocarditis is usually mild and recovery occurs within two weeks. Severe cases can lead to cardiac failure and death. Treatment consists of avoiding vigorous exercise, a low-salt diet, electrocardiographic monitoring, and treatment of the cardiac failure. Endocarditis (en'-ôi-kar-Di-tis) refers to an inflammation of the endocardium and typically involves the heart valves. Most cases are caused by bacteria (bacterial endocarditis). Signs and symptoms of endocarditis include fever, heart murmur, irregular or rapid heartbeat, fatigue, loss of appetite, night sweats, and chills. Treatment is with intravenous antibiotics.

Chambers of the Heart

The heart has four chambers. The two superior receiving chambers are the atria (= entry halls or chambers), and the two inferior pumping chambers are the ventricles (= little bellies). On the anterior surface of each atrium is a wrinkled pouchlike structure called an auricle (OR-i-kul; aurí- = ear), so named because of its resemblance to a dog’s ear (Figure 20.3). Each auricle slightly increases the capacity of an atrium so that it can hold a
Figure 20.3 Structure of the heart: surface features. Throughout this book, blood vessels that carry oxygenated blood (which looks bright red) are colored red, whereas those that carry deoxygenated blood (which looks dark red) are colored blue.

Sulci are grooves that contain blood vessels and fat and mark the external boundaries between the various chambers.

(a) Anterior external view showing surface features

(b) Anterior external view
greater volume of blood. Also on the surface of the heart are a series of grooves, called sulci (SUL-sē), that contain coronary blood vessels and a variable amount of fat. Each sulcus (SUL-kus) marks the external boundary between two chambers of the heart. The deep coronary sulcus (coron- = resembling a crown) encircles most of the heart and marks the external boundary between the superior atria and inferior ventricles. The anterior interventricular sulcus is a shallow groove on the anterior surface of the heart that marks the external boundary between the right and left ventricles. This sulcus continues around to the posterior surface of the heart as the posterior interventricular sulcus, which marks the external boundary between the ventricles on the posterior aspect of the heart (Figure 20.3c).

**Right Atrium**

The right atrium forms the right border of the heart and receives blood from three veins: the superior vena cava, inferior vena cava, and coronary sinus (Figure 20.4a) (Veins always return blood to the heart). The right atrium is about 2–3 mm (0.08–0.12 in.) in average thickness. The anterior and posterior walls of the right atrium are very different. The posterior wall is smooth; the anterior wall is rough due to the presence of muscular ridges called pectinate muscles (PEK-tin-āt; pectin = comb), which also extend into the auricle (Figure 20.4b). Between the right atrium and left atrium is a thin partition called the interatrial septum (inter- = between; septum = a dividing wall or partition). A prominent feature of this septum is an oval depression called the fossa ovalis, the remnant of the foramen ovale, an opening in the interatrial septum of the fetal heart that normally closes soon after birth (see Figure 21.30 on page 822). Blood passes from the right atrium into the right ventricle through a valve that is called the tricuspid valve (tri-KUS-pid; tri- = three; cuspid = point) because it consists of three leaflets or cusps (Figure 20.4a). It is also called the right atrioventricular valve. The valves of the heart are composed of dense connective tissue covered by endocardium.

**Right Ventricle**

The right ventricle is about 4–5 mm (0.16–0.2 in.) in average thickness and forms most of the anterior surface of the heart. The inside of the right ventricle contains a series of ridges formed by raised bundles of cardiac muscle fibers called trabeculae carneae (tra-BEK-ū-lē KAR-nē-ē; trabeculae = little beams; carneae = fleshy; see Figure 20.2a). Some of the trabeculae carneae convey part of the conduction system of the heart, which you will learn about later in this chapter (see page 732). The cusps of the tricuspid valve are connected to tendonlike cords, the chordae tendineae (KOR-dē ten-DIN-ē-ē; chordae = cord; tend- = tendon), which in turn are connected to cone-shaped trabeculae carneae called papillary muscles (papill- =...
Figure 20.4 Structure of the heart: internal anatomy.

Blood flows into the right atrium through the superior vena cava, inferior vena cava, and coronary sinus and into the left atrium through four pulmonary veins.
How does thickness of the myocardium relate to the workload of a cardiac chamber?

In the atria, blood is delivered under less pressure into the ventricles. Because the ventricles pump blood under higher pressure over greater distances, their walls are thicker. The right side of the heart has a much smaller workload, pumping blood a short distance to the lungs at lower pressure, with small resistance to blood flow. The left side pumps blood for all parts of the body at higher pressure, with resistance to blood flow.

**Left Atrium**

The left atrium is about the same thickness as the right atrium and forms most of the base of the heart. It receives blood from the lungs through four pulmonary veins. Like the right atrium, the inside of the left atrium has a smooth posterior wall. Because pectinate muscles are confined to the auricle of the left atrium, the anterior wall of the left atrium also is smooth. Blood passes from the left atrium into the left ventricle through the bicuspid (mitral) valve, which, as its name implies, has two cusps. The term mitral refers to the resemblance of the bicuspid valve to a bishop's miter hat. This is two-sided. It is also called the left atrioventricular valve.

**Left Ventricle**

The left ventricle is the thickest chamber of the heart, averaging 10–15 mm (0.4–0.6 in.) and forms the apex of the heart. Like the right ventricle, the left ventricle contains trabeculae carneae and has chordae tendineae that anchor the cusps of the bicuspid valve to papillary muscles. Blood passes from the left ventricle through the aortic valve into the ascending aorta, which branch from the ascending aorta and carry blood to the heart wall. The remainder of the blood passes into the arch of the aorta and descending aorta. Branches of the arch of the aorta and descending aorta carry blood throughout the body.

During fetal life, a temporary blood vessel, called the ductus arteriosus, shunts blood from the pulmonary trunk into the aorta. Hence, only a small amount of blood enters the nonfunctioning fetal lungs. The ductus arteriosus normally closes shortly after birth, leaving a remnant known as the ligamentum arteriosum, which connects the arch of the aorta and pulmonary trunk.

**Myocardial Thickness and Function**

The thickness of the myocardium of the four chambers varies according to each chamber's function. The thin-walled atria deliver blood under less pressure into the adjacent ventricles. Because the ventricles pump blood under higher pressure over greater distances, their walls are thicker. Although the right and left ventricles act as two separate pumps that simultaneously eject equal volumes of blood, the right side has a much smaller workload. It pumps blood a short distance to the lungs at lower pressure, whereas the resistance to blood flow is small. The left ventricle pumps blood to the body at higher pressure, and the resistance to blood flow is large.
flow is larger. Therefore, the left ventricle works much harder than the right ventricle to maintain the same rate of blood flow. The anatomy of the two ventricles confirms this functional difference—the muscular wall of the left ventricle is considerably thicker than the wall of the right ventricle (Figure 20.4c). Note also that the perimeter of the lumen (space) of the left ventricle is roughly circular in contrast to that of the right ventricle, which is somewhat crescent shaped.

Fibrous Skeleton of the Heart

In addition to cardiac muscle tissue, the heart wall also contains dense connective tissue that forms the fibrous skeleton of the heart (Figure 20.5). Essentially, the fibrous skeleton consists of four dense connective tissue rings that surround the valves of the heart, fuse with one another, and merge with the interventricular septum. In addition to forming a structural foundation for the heart valves, the fibrous skeleton prevents overstretching of the valves as blood passes through them. It also serves as a point of insertion for bundles of cardiac muscle fibers and acts as an electrical insulator between the atria and ventricles.

CHECKPOINT

1. Define each of the following external features of the heart: auricle, coronary sulcus, anterior interventricular sulcus, and posterior interventricular sulcus.
2. Describe the structure of the pericardium and the layers of the wall of the heart.
3. What are the characteristic internal features of each chamber of the heart?
4. Which blood vessels deliver blood to the right and left atria?
5. What is the relationship between wall thickness and function among the various chambers of the heart?
6. What type of tissue composes the fibrous skeleton of the heart? What functions does this tissue perform?

Figure 20.5  Fibrous skeleton of the heart. Elements of the fibrous skeleton are shown in capital letters.

Operation of the Semilunar Valves

The aortic and pulmonary valves are known as the **semilunar** (SL) valves (semi- = half; lunar = moon-shaped) because they are made up of three crescent moon-shaped cusps (Figure 20.6d). Each cusp attaches to the arterial wall by its convex outer margin. The SL valves allow ejection of blood from the heart into arteries but prevent backflow of blood into the ventricles. The free borders of the cusps project into the lumen of the artery. When the ventricles contract, pressure builds up within the chambers. The semilunar valves open when pressure in the ventricles exceeds the pressure in the arteries, permitting ejection of blood from the ventricles into the pulmonary trunk and aorta (Figure 20.6e). As the ventricles relax, blood starts to flow back toward the heart. This backflowing blood fills the valve cusps, which causes the semilunar valves to close tightly (Figure 20.6d).

Surprisingly perhaps, there are no valves guarding the junctions between the venae cavae and the right atrium or the pulmonary veins and the left atrium. As the atria contract, a small amount of blood does flow backward from the atria into these vessels. However, backflow is minimized by a different mechanism; as the atrial muscle contracts, it compresses and nearly collapses the venous entry points.

---

**CLINICAL CONNECTION | Heart Valve Disorders**

When heart valves operate normally, they open fully and close completely at the proper times. A narrowing of a heart valve opening that restricts blood flow is known as **stenosis** (ste-NO-sis = a narrowing); failure of a valve to close completely is termed **insufficiency** or **incompetence**. In **mitral stenosis**, scar formation or a congenital defect causes narrowing of the mitral valve. One cause of **mitral insufficiency**, in which there is backflow of blood from the left ventricle into the left atrium, is **mitral valve prolapse (MVP)**. In MVP one or both cusps of the mitral valve protrude into the left atrium during ventricular contraction. Mitral valve prolapse is one of the most common valvular disorders, affecting as much as 30% of the population. It is more prevalent in women than in men, and does not always pose a serious threat. In **aortic stenosis** the aortic valve is narrowed, and in **aortic insufficiency** there is backflow of blood from the aorta into the left ventricle.

Certain infectious diseases can damage or destroy the heart valves. One example is **rheumatic fever**, an acute systemic inflammatory disease that usually occurs after a streptococcal infection of the throat. The bacteria trigger an immune response in which antibodies produced to destroy the bacteria instead attack and inflame the connective tissues in joints, heart valves, and other organs. Even though rheumatic fever may weaken the entire heart wall, most often it damages the mitral and aortic valves.

---

? How do papillary muscles prevent atrioventricular valve cusps from evert (swinging upward) into the atria?
Systemic and Pulmonary Circulations

In postnatal (after birth) circulation, the heart pumps blood into two closed circuits with each beat—systemic circulation and pulmonary circulation (pulmon- = lung). The two circuits are arranged in series: The output of one becomes the input of the other, as would happen if you attached two garden hoses (see Figure 21.17 on page 000). The left side of the heart is the pump for systemic circulation; it receives bright red, oxygen-rich blood from the lungs. The left ventricle ejects blood into the aorta (Figure 20.7). From the aorta, the blood divides into separate streams, entering progressively smaller systemic arteries that carry it to all organs throughout the body—except for the air sacs (alveoli) of the lungs, which are supplied by pulmonary circulation. In systemic tissues, arteries give rise to smaller-diameter arterioles, which finally lead into extensive beds of systemic capillaries. Exchange of nutrients and gases occurs across the thin capillary walls. Blood unloads O₂ (oxygen) and picks up CO₂ (carbon dioxide). In most cases, blood flows through only one capillary and then enters a systemic venule. Venules carry deoxygenated (oxygen-poor) blood away from tissues and merge to form larger systemic veins. Ultimately the blood flows back to the right atrium.

The right side of the heart is the pump for pulmonary circulation; it receives all the dark red, deoxygenated blood returning from systemic circulation. Blood ejected from the right ventricle flows into the pulmonary trunk, which branches into pulmonary arteries that carry blood to the right and left lungs. In pulmonary capillaries, blood unloads CO₂, which is exhaled, and picks up inhaled O₂. The freshly oxygenated blood then flows into pulmonary veins and returns to the left atrium.

Coronary Circulation

Nutrients are not able to diffuse quickly enough from blood in the chambers of the heart to supply all the layers of cells that make up the heart wall. For this reason, the myocardium has its own network of blood vessels, the coronary or cardiac circulation (coron- = crown). The coronary arteries branch from the ascending aorta and encircle the heart like a crown encircles the head (Figure 20.8a). While the heart is contracting, little blood flows in the coronary arteries because they are squeezed shut. When the heart relaxes, however, the high pressure of blood in the aorta propels blood through the coronary arteries into capillaries, and then into coronary veins (Figure 20.8b).

Coronary Arteries

Two coronary arteries, the right and left coronary arteries, branch from the ascending aorta and supply oxygenated blood to the myocardium (Figure 20.8a). The left coronary artery passes inferior to the left auricle and divides into the anterior interventricular and circumflex branches. The anterior interventricular branch or left anterior descending (LAD) artery is in the anterior interventricular sulcus and supplies oxygenated blood to the walls of both ventricles. The circumflex branch lies in the coronary sulcus and distributes oxygenated blood to the walls of the left ventricle and left atrium.

The right coronary artery supplies small branches (atrial branches) to the right aurium. It continues inferior to the right auricle and ultimately divides into the posterior interventricular and marginal branches. The posterior interventricular branch follows the posterior interventricular sulcus and supplies the
Which coronary blood vessel delivers oxygenated blood to the walls of the left atrium and left ventricle?
walls of the two ventricles with oxygenated blood. The marginal branch in the coronary sulcus transports oxygenated blood to the myocardium of the right ventricle.

Most parts of the body receive blood from branches of more than one artery, and where two or more arteries supply the same region, they usually connect. These connections, called anastomoses (ə-nas′tō-MÔ-sēz), provide alternate routes called collateral circuits, for blood to reach a particular organ or tissue. The myocardium contains many anastomoses that connect branches of a given coronary artery or extend between branches of different coronary arteries. They provide detours for arterial blood if a main route becomes obstructed. Thus, heart muscle may receive sufficient oxygen even if one of its coronary arteries is partially blocked.

**Coronary Veins**

After blood passes through the arteries of the coronary circulation, it flows into capillaries, where it delivers oxygen and nutrients to the heart muscle and collects carbon dioxide and waste, and then moves into coronary veins. Most of the deoxygenated blood from the myocardium drains into a large vascular sinus in the coronary sulcus on the posterior surface of the heart, called the coronary sinus (Figure 20.8b). (A vascular sinus is a thin-walled vein that has no smooth muscle to alter its diameter.) The deoxygenated blood in the coronary sinus empties into the right atrium. The principal tributaries carrying blood into the coronary sinus are the following:

- **Great cardiac vein** in the anterior interventricular sulcus, which drains the areas of the heart supplied by the left coronary artery (left and right ventricles and left atrium)
- **Middle cardiac vein** in the posterior interventricular sulcus, which drains the areas supplied by the posterior interventricular branch of the right coronary artery (left and right ventricles)
- **Small cardiac vein** in the coronary sulcus, which drains the right atrium and right ventricle
- **Anterior cardiac veins**, which drain the right ventricle and open directly into the right atrium

When blockage of a coronary artery deprives the heart muscle of oxygen, reperfusion, the reestablishment of blood flow, may damage the tissue further. This surprising effect is due to the formation of oxygen free radicals from the reintroduced oxygen. As you learned in Chapter 2, free radicals are electrically charged molecules that have an unpaired electron (see Figure 2.3b on page 000). These unstable, highly reactive molecules cause chain reactions that lead to cellular damage and death. To counter the effects of oxygen free radicals, body cells produce enzymes that convert free radicals to less reactive substances. Two such enzymes are superoxide dismutase and catalase. In addition, nutrients such as vitamin E, vitamin C, beta-carotene, zinc, and selenium serve as antioxidants, which remove oxygen free radicals from circulation. Drugs that lessen reperfusion damage after a heart attack or stroke are currently under development.

**CHECKPOINT**

7. What causes the heart valves to open and to close? What supporting structures ensure that the valves operate properly?
8. In correct sequence, which heart chambers, heart valves, and blood vessels would a drop of blood encounter as it flows from the right atrium to the aorta?
9. Which arteries deliver oxygenated blood to the myocardium of the left and right ventricles?

**CARDIAC MUSCLE TISSUE AND THE CARDIAC CONDUCTION SYSTEM**

**OBJECTIVES**

- Describe the structural and functional characteristics of cardiac muscle tissue and the conduction system of the heart.
- Explain how an action potential occurs in cardiac contractile fibers.
- Describe the electrical events of a normal electrocardiogram (ECG).
Histology of Cardiac Muscle Tissue

Compared with skeletal muscle fibers, cardiac muscle fibers are shorter in length and less circular in transverse section (Figure 20.9). They also exhibit branching, which gives individual cardiac muscle fibers a “stair-step” appearance (see Table 4.5B on page 138). A typical cardiac muscle fiber is 50–100 µm long and

**Figure 20.9** Histology of cardiac muscle tissue. (See Table 4.5B on page 138 for a light micrograph of cardiac muscle.)

Cardiac muscle fibers connect to neighboring fibers by intercalated discs, which contain desmosomes and gap junctions.

What are the functions of intercalated discs in cardiac muscle fibers?

?
has a diameter of about 14 \mu m. Usually one centrally located nucleus is present, although an occasional cell may have two nuclei. The ends of cardiac muscle fibers connect to neighboring fibers by irregular transverse thickenings of the sarcolemma called intercalated discs (in-TÉR-ká-lät-ed; intercalated = to insert between). The discs contain desmosomes, which hold the fibers together, and gap junctions, which allow muscle action potentials to conduct from one muscle fiber to its neighbors. Gap junctions allow the entire myocardium of the atria or the ventricles to contract as a single, coordinated unit.

Mitochondria are larger and more numerous in cardiac muscle fibers than in skeletal muscle fibers. In a cardiac muscle fiber, they take up 25% of the cytosolic space; in a skeletal muscle fiber only 2% of the cytosolic space is occupied by mitochondria. Cardiac muscle fibers have the same arrangement of actin and myosin, and the same bands, zones, and Z discs, as skeletal muscle fibers. The transverse tubules of cardiac muscle are wider but less abundant than those of skeletal muscle; the one transverse tubule per sarcomere is located at the Z disc. The sarcoplasmic reticulum of cardiac muscle fibers is somewhat smaller than the SR of skeletal muscle fibers. As a result, cardiac muscle has a smaller intracellular reserve of Ca^{2+}.

---

**Clinical Connection**

**Regeneration of Heart Cells**

As noted earlier in the chapter, the heart of a heart attack survivor often has regions of infarcted (dead) cardiac muscle tissue that typically are replaced with noncontractile fibrous scar tissue over time. Our inability to repair damage from a heart attack has been attributed to a lack of stem cells in cardiac muscle and to the absence of mitosis in mature cardiac muscle fibers. A recent study of heart transplant recipients by American and Italian scientists, however, provides evidence for significant replacement of heart cells. The researchers studied men who had received a heart from a female, and then looked for the presence of X chromosomes and lack the Y chromosome. (All female cells except gametes have two X chromosomes and lack the Y chromosome.) Several years after the transplant surgery, between 7% and 16% of the heart cells in the transplanted tissue, including cardiac muscle fibers and endothelial cells in coronary arteries and capillaries, had been replaced by the recipient’s own cells, as evidenced by the presence of a Y chromosome. The study also revealed cells with some of the characteristics of stem cells in both transplanted hearts and control hearts. Evidently, stem cells can migrate from the blood into the heart and differentiate into functional muscle and endothelial cells. The hope is that researchers can learn how to “turn on” such regeneration of heart cells to treat people with heart failure or cardiomyopathy (diseased heart).

---

**Autorhythmic Fibers: The Conduction System**

An inherent and rhythmical electrical activity is the reason for the heart’s lifelong beat. The source of this electrical activity is a network of specialized cardiac muscle fibers called autorhythmic fibers (auto- = self) because they are self-excitatory. Autorhythmic fibers repeatedly generate action potentials that trigger heart contractions. They continue to stimulate a heart to beat even after it is removed from the body—for example, to be transplanted into another person—and all of its nerves have been cut. (Note: Surgeons do not attempt to reattach heart nerves during heart transplant operations. For this reason, it has been said that heart surgeons are better “plumbers” than they are “electricians.”)

During embryonic development, only about 1% of the cardiac muscle fibers become autorhythmic fibers; these relatively rare fibers have two important functions.

1. They act as a pacemaker, setting the rhythm of electrical excitation that causes contraction of the heart.
2. They form the conduction system, a network of specialized cardiac muscle fibers that provide a path for each cycle of cardiac excitation to progress through the heart. The conduction system ensures that cardiac chambers become stimulated to contract in a coordinated manner, which makes the heart an effective pump.

As you will see later in the chapter, problems with autorhythmic fibers can result in arrhythmias (abnormal rhythms) in which the heart beats irregularly, too fast, or too slow.

Cardiac action potentials propagate through the conduction system in the following sequence (Figure 20.10a):

1. Cardiac excitation normally begins in the sinoatrial (SA) node, located in the right atrial wall just inferior and lateral to the opening of the superior vena cava. SA node cells do not have a stable resting potential. Rather, they repeatedly depolarize to threshold spontaneously. The spontaneous depolarization is a pacemaker potential. When the pacemaker potential reaches threshold, it triggers an action potential (Figure 20.10b). Each action potential from the SA node propages throughout both atria via gap junctions in the intercalated discs of atrial muscle fibers. Following the action potential, the atria contract.
2. By conducting along atrial muscle fibers, the action potential reaches the atrioventricular (AV) node, located in the interatrial septum, just anterior to the opening of the coronary sinus (Figure 20.10a).
3. From the AV node, the action potential enters the atrioventricular (AV) bundle (also known as the bundle of His). This bundle is the only site where action potentials can conduct from the atria to the ventricles. (Elsewhere, the fibrous skeleton of the heart electrically insulates the atria from the ventricles.)
4. After propagating along the AV bundle, the action potential enters both the right and left bundle branches. The bundle branches extend through the interventricular septum toward the apex of the heart.
5. Finally, the large-diameter Purkinje fibers rapidly conduct the action potential beginning at the apex of the heart upward to the remainder of the ventricular myocardium. Then the ventricles contract, pushing the blood upward toward the semilunar valves.
On their own, autorhythmic fibers in the SA node would initiate an action potential about every 0.6 second, or 100 times per minute. This rate is faster than that of any other autorhythmic fibers. Because action potentials from the SA node spread through the conduction system and stimulate other areas before the other areas are able to generate an action potential at their own, slower rate, the SA node acts as the natural pacemaker of the heart. Nerve impulses from the autonomic nervous system (ANS) and blood-borne hormones (such as epinephrine) modify the timing and strength of each heartbeat, but they do not establish the fundamental rhythm. In a person at rest, for example, acetylcholine released by the parasympathetic division of the ANS slows SA node pacing to about every 0.8 second or 75 action potentials per minute (Figure 20.10b).

**Figure 20.10** The conduction system of the heart. Autorhythmic fibers in the SA node, located in the right atrial wall (a), act as the heart’s pacemaker, initiating cardiac action potentials (b) that cause contraction of the heart’s chambers.

The conduction system ensures that the chambers of the heart contract in a coordinated manner.

---

**Which component of the conduction system provides the only electrical connection between the atria and the ventricles?**

---

**ANATOMY**

1. SINOATRIAL (SA) NODE
2. ATRIOVENTRICULAR (AV) NODE
3. ATRIOVENTRICULAR (AV) BUNDLE (BUNDLE OF HIS)
4. RIGHT AND LEFT BUNDLE BRANCHES
5. PURKINJE FIBERS

**FUNCTIONS**

- **SA Node:** Initiates cardiac action potentials.
- **AV Node:** Acts as the heart's pacemaker, initiating action potentials.
- **ATRIOVENTRICULAR BUNDLE:** Conveys action potentials to the ventricles.
- **PURKINJE FIBERS:** Conduct action potentials to the ventricles for effective contraction.

Action Potential and Contraction of Contractile Fibers

The action potential initiated by the SA node travels along the conduction system and spreads out to excite the “working” atrial and ventricular muscle fibers, called contractile fibers. An action potential occurs in a contractile fiber as follows (Figure 20.11):

1. **Depolarization.** Unlike autorhythmic fibers, contractile fibers have a stable resting membrane potential that is close to $-90$ mV. When a contractile fiber is brought to threshold by an action potential from neighboring fibers, its **voltage-gated fast Na$^+$ channels** open. These sodium ion channels are referred to as “fast” because they open very rapidly in response to a threshold-level depolarization. Opening of these channels allows Na$^+$ inflow because the cytosol of contractile fibers is electrically more negative than interstitial fluid and Na$^+$ concentration is higher in interstitial fluid. Inflow of Na$^+$ down the electrochemical gradient produces a rapid depolarization. Within a few milliseconds, the fast Na$^+$ channels automatically inactivate and Na$^+$ inflow decreases.

2. **Plateau.** The next phase of an action potential in a contractile fiber is the **plateau**, a period of maintained depolarization. It is due in part to opening of **voltage-gated slow Ca$^{2+}$ channels** in the sarcolemma. When these channels open, calcium ions move from the interstitial fluid (which has a higher Ca$^{2+}$ concentration) into the cytosol. This inflow of Ca$^{2+}$ causes even more Ca$^{2+}$ to pour out of the sarcoplasmic reticulum into the cytosol through additional Ca$^{2+}$ channels in the sarcoplasmic reticulum membrane. The increased Ca$^{2+}$ concentration in the cytosol ultimately triggers contraction. Several different types of **voltage-gated K$^+$ channels** are also found in the sarcolemma of a contractile fiber. Just before the plateau phase begins, some of these K$^+$ channels open, allowing potassium ions to leave the contractile fiber. Therefore, depolarization is sustained during the plateau phase because Ca$^{2+}$ inflow just balances K$^+$ outflow. The plateau phase lasts for about 0.25 sec, and the membrane potential of the contractile fiber is close to 0 mV. By comparison, depolarization in a neuron or skeletal muscle

---

**Figure 20.11** Action potential in a ventricular contractile fiber. The resting membrane potential is about $-90$ mV.

- **Depolarization** due to Na$^+$ inflow when voltage-gated fast Na$^+$ channels open
- **Plateau** (maintained depolarization) due to Ca$^{2+}$ inflow when voltage-gated slow Ca$^{2+}$ channels open and K$^+$ outflow when some K$^+$ channels open
- **Repolarization** due to closure of Ca$^{2+}$ channels and K$^+$ outflow when additional voltage-gated K$^+$ channels open

How does the duration of an action potential in a ventricular contractile fiber compare with that in a skeletal muscle fiber?
fiber is much briefer, about 1 msec (0.001 sec), because it lacks a plateau phase.

3 Repolarization. The recovery of the resting membrane potential during the repolarization phase of a cardiac action potential resembles that in other excitable cells. After a delay (which is particularly prolonged in cardiac muscle), additional voltage-gated K⁺ channels open. Outflow of K⁺ restores the negative resting membrane potential (−90 mV).

At the same time, the calcium channels in the sarclemma and the sarcoplasmic reticulum are closing, which also contributes to repolarization.

The mechanism of contraction is similar in cardiac and skeletal muscle: The electrical activity (action potential) leads to the mechanical response (contraction) after a short delay. As Ca²⁺ concentration rises inside a contractile fiber, Ca²⁺ binds to the regulatory protein troponin, which allows the actin and myosin filaments to begin sliding past one another, and tension starts to develop. Substances that alter the movement of Ca²⁺ through slow Ca²⁺ channels influence the strength of heart contractions. Epinephrine, for example, increases contraction force by enhancing Ca²⁺ flow into the cytosol.

In muscle, the refractory period is the time interval during which a second contraction cannot be triggered. The refractory period of a cardiac muscle fiber lasts longer than the contraction itself (Figure 20.11). As a result, another contraction cannot begin until relaxation is well underway. For this reason, tetanus (maintained contraction) cannot occur in cardiac muscle as it can in skeletal muscle. The advantage is apparent if you consider how the ventricles work. Their pumping function depends on alternating contraction (when they eject blood) and relaxation (when they refill). If heart muscle could undergo tetanus, blood flow would cease.

ATP Production in Cardiac Muscle

In contrast to skeletal muscle, cardiac muscle produces little of the ATP it needs by anaerobic cellular respiration (see Figure 10.12 on page 319). Instead, it relies almost exclusively on aerobic cellular respiration in its numerous mitochondria. The needed oxygen diffuses from blood in the coronary circulation and is released from myoglobin inside cardiac muscle fibers. Cardiac muscle fibers use several fuels to power mitochondrial ATP production. In a person at rest, the heart’s ATP comes mainly from oxidation of fatty acids (60%) and glucose (35%), with smaller contributions from lactic acid, amino acids, and ketone bodies. During exercise, the heart’s use of lactic acid, produced by actively contracting skeletal muscles, rises.

Like skeletal muscle, cardiac muscle also produces some ATP from creatine phosphate. One sign that a myocardial infarction (heart attack, see page 730) has occurred is the presence in blood of creatine kinase (CK), the enzyme that catalyzes transfer of a phosphate group from creatine phosphate to ADP to make ATP. Normally, CK and other enzymes are confined within cells. Injured or dying cardiac or skeletal muscle fibers release CK into the blood.

Electrocardiogram

As action potentials propagate through the heart, they generate electrical currents that can be detected at the surface of the body. An electrocardiogram (e-lek’-trō-KAR-dē-ō-gram), abbreviated either ECG or EKG (from the German word Elektrokardiogram), is a recording of these electrical signals. The ECG is a composite record of action potentials produced by all the heart muscle fibers during each heartbeat. The instrument used to record the changes is an electrocardiograph.

In clinical practice, electrodes are positioned on the arms and legs (limb leads) and at six positions on the chest (chest leads) to record the ECG. The electrocardiograph amplifies the heart’s electrical signals and produces 12 different tracings from different combinations of limb and chest leads. Each limb and chest electrode records slightly different electrical activity because of the difference in its position relative to the heart. By comparing these records with one another and with normal records, it is possible to determine (1) if the conducting pathway is abnormal, (2) if the heart is enlarged, (3) if certain regions of the heart are damaged, and (4) the cause of chest pain.

In a typical record, three clearly recognizable waves appear with each heartbeat (Figure 20.12). The first, called the P wave, is a small upward deflection on the ECG. The P wave represents atrial depolarization, which spreads from the SA

Figure 20.12 Normal electrocardiogram or ECG (Lead II).

P wave = atrial depolarization; QRS complex = onset of ventricular depolarization; T wave = ventricular repolarization.

What is the significance of an enlarged Q wave?
node through contractile fibers in both atria. The second wave, called the QRS complex, begins as a downward deflection, continues as a large, upright, triangular wave, and ends as a downward wave. The QRS complex represents rapid ventricular depolarization, as the action potential spreads through ventricular contractile fibers. The third wave is a dome-shaped upward deflection called the T wave. It indicates ventricular repolarization and occurs just as the ventricles are starting to relax. The T wave is smaller and wider than the QRS complex because repolarization occurs more slowly than depolarization. During the plateau period of steady depolarization, the ECG tracing is flat.

In reading an ECG, the size of the waves can provide clues to abnormalities. Larger P waves indicate enlargement of an atrium; an enlarged Q wave may indicate a myocardial infarction; and an enlarged R wave generally indicates enlarged ventricles. The T wave is flatter than normal when the heart muscle is receiving insufficient oxygen—as, for example, in coronary artery disease. The T wave may be elevated in hyperkalemia (high blood K⁺ level).

Analysis of an ECG also involves measuring the time spans between waves, which are called intervals or segments. For example, the P-Q interval is the time from the beginning of the P wave to the beginning of the QRS complex. It represents the conduction time from the beginning of atrial excitation to the beginning of ventricular excitation. Put another way, the P-Q interval is the time required for the action potential to travel through the atria, atrioventricular node, and the remaining fibers of the conduction system. As the action potential is forced to detour around scar tissue caused by disorders such as coronary artery disease and rheumatic fever, the P-Q interval lengthens.

The S-T segment, which begins at the end of the S wave and ends at the beginning of the T wave, represents the time when the ventricular contractile fibers are depolarized during the plateau phase of the action potential. The S-T segment is elevated (above the baseline) in acute myocardial infarction and depressed (below the baseline) when the heart muscle receives insufficient oxygen. The Q-T interval extends from the start of the QRS complex to the end of the T wave. It is the time from the beginning of ventricular depolarization to the end of ventricular repolarization. The Q-T interval may be lengthened by myocardial damage, myocardial ischemia (decreased blood flow), or conduction abnormalities.

Sometimes it is helpful to evaluate the heart’s response to the stress of physical exercise (stress testing) (see page 751). Although narrowed coronary arteries may carry adequate oxygenated blood while a person is at rest, they will not be able to meet the heart’s increased need for oxygen during strenuous exercise. This situation creates changes that can be seen on an electrocardiogram.

Abnormal heart rhythms and inadequate blood flow to the heart may occur only briefly or unpredictably. To detect these problems, continuous ambulatory electrocardiographs are used. With this procedure, a person wears a battery-operated monitor (Holter monitor) that records an ECG continuously for 24 hours. Electrodes attached to the chest are connected to the monitor, and information on the heart’s activity is stored in the monitor and retrieved later by medical personnel.

**Correlation of ECG Waves with Atrial and Ventricular Systole**

As we have seen, the atria and ventricles depolarize and then contract at different times because the conduction system routes cardiac action potentials along a specific pathway. The term systole (SIS-t ô-lé = contraction) refers to the phase of contraction; the phase of relaxation is diastole (di-AS-tô-lé = dilation or expansion). The ECG waves predict the timing of atrial and ventricular systole and diastole. At a heart rate of 75 beats per minute, the timing is as follows (Figure 20.13):

1. A cardiac action potential arises in the SA node. It propagates throughout the atrial muscle and down to the AV node in about 0.03 sec. As the atrial contractile fibers depolarize, the P wave appears in the ECG.
2. After the P wave begins, the atria contract (atrial systole). Conduction of the action potential slows at the AV node because the fibers there have much smaller diameters and fewer gap junctions. (Traffic slows in a similar way where a four-lane highway narrows to one lane in a construction zone!) The resulting 0.1-sec delay gives the atrial time to contract, thus adding to the volume of blood in the ventricles, before ventricular systole begins.
3. The action potential propagates rapidly again after entering the AV bundle. About 0.2 sec after onset of the P wave, it has propagated through the bundle branches, Purkinje fibers, and the entire ventricular myocardium. Depolarization progresses down the septum, upward from the apex, and outward from the endocardial surface, producing the QRS complex. At the same time, atrial repolarization is occurring, but it is not usually evident in an ECG because the larger QRS complex masks it.
4. Contraction of ventricular contractile fibers (ventricular systole) begins shortly after the QRS complex appears and continues during the S-T segment. As contraction proceeds from the apex toward the base of the heart, blood is squeezed upward toward the semilunar valves.
5. Repolarization of ventricular contractile fibers begins at the apex and spreads throughout the ventricular myocardium. This produces the T wave in the ECG about 0.4 sec after the onset of the P wave.
6. Shortly after the T wave begins, the ventricles start to relax (ventricular diastole). By 0.6 sec, ventricular repolarization is complete and ventricular contractile fibers are relaxed.

During the next 0.2 sec, contractile fibers in both the atria and ventricles are relaxed. At 0.8 sec, the P wave appears again in the ECG, the atria begin to contract, and the cycle repeats.

As you have just learned, events in the heart occur in cycles that repeat for as long as you live. Next, we will see how the
Figure 20.13 Timing and route of action potential depolarization and repolarization through the conduction system and myocardium. Green indicates depolarization and red indicates repolarization.

Depolarization causes contraction and repolarization causes relaxation of cardiac muscle fibers.

1. Depolarization of atrial contractile fibers produces P wave
2. Atrial systole (contraction)
3. Depolarization of ventricular contractile fibers produces QRS complex
4. Ventricular systole (contraction)
5. Repolarization of ventricular contractile fibers produces T wave
6. Ventricular diastole (relaxation)

Where in the conduction system do action potentials propagate most slowly?
pressure changes associated with relaxation and contraction of the heart chambers allow the heart to alternately fill with blood and then eject blood into the aorta and pulmonary trunk.

**CHECKPOINT**

1. How do cardiac muscle fibers differ structurally and functionally from skeletal muscle fibers?
2. In what ways are autorhythmic fibers similar to and different from contractile fibers?
3. What happens during each of the three phases of an action potential in ventricular contractile fibers?
4. In what ways are ECGs helpful in diagnosing cardiac problems?
5. How does each ECG wave, interval, and segment relate to contraction (systole) and relaxation (diastole) of the atria and ventricles?

**THE CARDIOVASCULAR SYSTEM: THE HEART**

**OBJECTIVES**

- Describe the pressure and volume changes that occur during a cardiac cycle.
- Relate the timing of heart sounds to the ECG waves and pressure changes during systole and diastole.

A single cardiac cycle includes all the events associated with one heartbeat. Thus, a cardiac cycle consists of systole and diastole of the atria plus systole and diastole of the ventricles.

**Pressure and Volume Changes During the Cardiac Cycle**

In each cardiac cycle, the atria and ventricles alternately contract and relax, forcing blood from areas of higher pressure to areas of lower pressure. As a chamber of the heart contracts, blood pressure within it increases. Figure 20.14 shows the relation between the heart’s electrical signals (ECG) and changes in atrial pressure, ventricular pressure, aortic pressure, and ventricular volume during the cardiac cycle. The pressures given in Figure 20.14 apply to the left side of the heart; pressures on the right side are considerably lower. Each ventricle, however, expels the same volume of blood per beat, and the same pattern exists for both pumping chambers. When heart rate is 75 beats/min, a cardiac cycle lasts 0.8 sec. To examine and correlate the events taking place during a cardiac cycle, we will begin with atrial systole.

**Atrial Systole**

During atrial systole, which lasts about 0.1 sec, the atria are contracting. At the same time, the ventricles are relaxed.

1. Depolarization of the SA node causes atrial depolarization, marked by the P wave in the ECG.
2. Atrial depolarization causes atrial systole. As the atria contract, they exert pressure on the blood within, which forces blood through the open AV valves into the ventricles.
3. Atrial systole contributes a final 25 mL of blood to the volume already in each ventricle (about 105 mL). The end of atrial systole is also the end of ventricular diastole (relaxation). Thus, each ventricle contains about 130 mL at the end of its relaxation period (diastole). This blood volume is called the end-diastolic volume (EDV).
4. The QRS complex in the ECG marks the onset of ventricular depolarization.

**Ventricular Systole**

During ventricular systole, which lasts about 0.3 sec, the ventricles are contracting. At the same time, the atria are relaxed in atrial diastole.

5. Ventricular depolarization causes ventricular systole. As ventricular systole begins, pressure rises inside the ventricles and pushes blood up against the atrioventricular (AV) valves, forcing them shut. For about 0.05 seconds, both the SL (semilunar) and AV valves are closed. This is the period of isovolumetric contraction (iso- = same). During this interval, cardiac muscle fibers are contracting and exerting force but are not yet shortening. Thus, the muscle contraction is isometric (same length). Moreover, because all four valves are closed, ventricular volume remains the same (isovolumic).

6. Continued contraction of the ventricles causes pressure inside the chambers to rise sharply. When left ventricular pressure surpasses aortic pressure at about 80 millimeters of mercury (mmHg) and right ventricular pressure rises above the pressure in the pulmonary trunk (about 20 mmHg), both SL valves open. At this point, ejection of blood from the heart begins. The period when the SL valves are open is ventricular ejection and lasts for about 0.25 sec. The pressure in the left ventricle continues to rise to about 120 mmHg, whereas the pressure in the right ventricle climbs to about 25–30 mmHg.

7. The left ventricle ejects about 70 mL of blood into the aorta and the right ventricle ejects the same volume of blood into the pulmonary trunk. The volume remaining in each ventricle at the end of systole, about 60 mL, is the end-systolic volume (ESV). Stroke volume, the volume ejected per beat from each ventricle, equals end-diastolic volume minus end-systolic volume: SV = EDV − ESV. At rest, the stroke volume is about 130 mL − 60 mL = 70 mL (a little more than 2 oz).

8. The T wave in the ECG marks the onset of ventricular repolarization.

**Relaxation Period**

During the relaxation period, which lasts about 0.4 sec, the atria and the ventricles are both relaxed. As the heart beats faster and faster, the relaxation period becomes shorter and shorter, whereas the durations of atrial systole and ventricular systole shorten only slightly.

9. Ventricular repolarization causes ventricular diastole. As the ventricles relax, pressure within the chambers falls, and
The Cardiac Cycle

A cardiac cycle is composed of all the events associated with one heartbeat.

(a) ECG

(b) Changes in left atrial pressure (green line), left ventricular pressure (blue line), and aortic pressure (red line) as they relate to the opening and closing of heart valves.

(c) Heart sounds.

(d) Changes in left ventricular volume.

(e) Phases of the cardiac cycle.

How much blood remains in each ventricle at the end of ventricular diastole in a resting person? What is this volume called?
Heart Sounds

Auscultation (aws-kul-TĀ-shun; auscultate- = listening), the act of listening to sounds within the body, is usually done with a stethoscope. The sound of the heartbeat comes primarily from blood turbulence caused by the closing of the heart valves. Smoothly flowing blood is silent. Compare the sounds made by white-water rapids or a waterfall with the silence of a smoothly flowing river. During each cardiac cycle, there are four heart sounds, but in a normal heart only the first and second heart sounds (S1 and S2) are loud enough to be heard through a stethoscope. Figure 20.14c shows the timing of heart sounds relative to other events in the cardiac cycle.

The first sound (S1), which can be described as a lub sound, is louder and a bit longer than the second sound. S1 is caused by blood turbulence associated with closure of the AV valves soon after ventricular systole begins. The second sound (S2), which is shorter and not as loud as the first, can be described as a dupp sound. S2 is caused by blood turbulence associated with closure of the SL valves at the beginning of ventricular diastole. Although S1 and S2 are due to blood turbulence associated with the closure of valves, they are best heard at the surface of the chest in locations that are slightly different from the locations of the valves (Figure 20.15). This is because the sound is carried by the blood flow away from the valves. Normally not loud enough to be heard, S3 is due to blood turbulence during rapid ventricular filling, and S4 is due to blood turbulence during atrial systole.

CLINICAL CONNECTION Heart Murmurs

Heart sounds provide valuable information about the mechanical operation of the heart. A heart murmur is an abnormal sound consisting of a clicking, rushing, or gurgling noise that either is heard before, between, or after the normal heart sounds, or may mask the normal heart sounds. Heart murmurs in children are extremely common and usually do not represent a health condition. Murmurs are most frequently discovered in children between the ages of two and four. These types of heart murmurs are referred to as innocent or functional heart murmurs; they often subside or disappear with growth. Although some heart murmurs in adults are innocent, most often an adult murmur indicates a valve disorder. When a heart valve exhibits stenosis, the heart murmur is heard while the valve should be fully open but is not. For example, mitral stenosis (see page 727) produces a murmur during the relaxation period, between S2 and the next S1. An incompetent heart valve, by contrast, causes a murmur to appear when the valve should be fully closed but is not. So, a murmur due to mitral incompetence (see page 727) occurs during ventricular systole, between S1 and S2.

• CLINICAL CONNECTION Heart Murmurs

Heart sounds provide valuable information about the mechanical operation of the heart. A heart murmur is an abnormal sound consisting of a clicking, rushing, or gurgling noise that either is heard before, between, or after the normal heart sounds, or may mask the normal heart sounds. Heart murmurs in children are extremely common and usually do not represent a health condition. Murmurs are most frequently discovered in children between the ages of two and four. These types of heart murmurs are referred to as innocent or functional heart murmurs; they often subside or disappear with growth. Although some heart murmurs in adults are innocent, most often an adult murmur indicates a valve disorder. For example, mitral stenosis (see page 727) produces a murmur during the relaxation period, between S2 and the next S1. An incompetent heart valve, by contrast, causes a murmur to appear when the valve should be fully closed but is not. So, a murmur due to mitral incompetence (see page 727) occurs during ventricular systole, between S1 and S2.

CHECKPOINT

15. Why must left ventricular pressure be greater than aortic pressure during ventricular ejection?
16. Does more blood flow through the coronary arteries during ventricular diastole or ventricular systole? Explain your answer.
17. During which two periods of the cardiac cycle do the heart muscle fibers exhibit isometric contractions?
18. What events produce the four normal heart sounds? Which ones can usually be heard through a stethoscope?

Figure 20.15 Heart sounds. Location of valves (purple) and auscultation sites (red) for heart sounds.

Listening to sounds within the body is called auscultation; it is usually done with a stethoscope.
CARDIAC OUTPUT

OBJECTIVES

- Define cardiac output.
- Describe the factors that affect regulation of stroke volume.
- Outline the factors that affect the regulation of heart rate.

Although the heart has autorhythmic fibers that enable it to beat independently, its operation is governed by events occurring throughout the body. All body cells must receive a certain amount of oxygen each minute to maintain health and life. When cells are metabolically active, as during exercise, they take up even more oxygen from the blood. During rest periods, cellular metabolic need is reduced, and the workload of the heart decreases.

Cardiac output (CO) is the volume of blood ejected from the left ventricle (or the right ventricle) into the aorta (or pulmonary trunk) each minute. Cardiac output equals the stroke volume (SV), the volume of blood ejected by the ventricle during each contraction, multiplied by the heart rate (HR), the number of heartbeats per minute:

\[
\text{CO} = \frac{\text{SV}}{\text{HR}} \\
(\text{mL/min}) = (\text{mL/beat}) \times (\text{beats/min})
\]

In a typical resting adult male, stroke volume averages 70 mL/beat, and heart rate is about 75 beats/min. Thus, average cardiac output is

\[
\text{CO} = \frac{70 \text{ mL/beat}}{75 \text{ beats/min}} = 5.25 \text{ L/min}
\]

This volume is close to the total blood volume, which is about 5 liters in a typical adult male. Thus, your entire blood volume flows through your pulmonary and systemic circulations each minute. Factors that increase stroke volume or heart rate normally increase CO. During mild exercise, for example, stroke volume may increase to 100 mL/beat, and heart rate to 100 beats/min. Cardiac output then would be 10 L/min. During intense (but still not maximal) exercise, the heart rate may accelerate to 150 beats/min, and stroke volume may rise to 130 mL/beat, resulting in a cardiac output of 19.5 L/min.

Cardiac reserve is the difference between a person’s maximum cardiac output and cardiac output at rest. The average person has a cardiac reserve of four or five times the resting value. Top endurance athletes may have a cardiac reserve seven or eight times their resting CO. People with severe heart disease may have little or no cardiac reserve, which limits their ability to carry out even the simple tasks of daily living.

Regulation of Stroke Volume

A healthy heart will pump out the blood that entered its chambers during the previous diastole. In other words, if more blood returns to the heart during diastole, then more blood is ejected during the next systole. At rest, the stroke volume is 50–60% of the end-diastolic volume because 40–50% of the blood remains in the ventricles after each contraction (end-systolic volume). Three factors regulate stroke volume and ensure that the left and right ventricles pump equal volumes of blood: (1) preload, the degree of stretch on the heart before it contracts; (2) contractility, the forcefulness of contraction of individual ventricular muscle fibers; and (3) afterload, the pressure that must be exceeded before ejection of blood from the ventricles can occur.

Preload: Effect of Stretching

A greater preload (stretch) on cardiac muscle fibers prior to contraction increases their force of contraction. Preload can be compared to the stretching of a rubber band. The more the rubber band is stretched, the more forcefully it will snap back. Within limits, the more the heart fills with blood during diastole, the greater the force of contraction during systole. This relationship is known as the Frank–Starling law of the heart. The preload is proportional to the end-diastolic volume (EDV) (the volume of blood that fills the ventricles at the end of diastole). Normally, the greater the EDV, the more forceful the next contraction.

Two key factors determine EDV: (1) the duration of ventricular diastole and (2) venous return, the volume of blood returning to the right ventricle. When heart rate increases, the duration of diastole is shorter. Less filling time means a smaller EDV, and the ventricles may contract before they are adequately filled. By contrast, when venous return increases, a greater volume of blood flows into the ventricles, and the EDV is increased.

When heart rate exceeds about 160 beats/min, stroke volume usually declines due to the short filling time. At such rapid heart rates, EDV is less, and the preload is lower. People who have slow resting heart rates usually have large resting stroke volumes because filling time is prolonged and preload is larger.

The Frank–Starling law of the heart equalizes the output of the right and left ventricles and keeps the same volume of blood flowing to both the systemic and pulmonary circulations. If the left side of the heart pumps a little more blood than the right side, the volume of blood returning to the right ventricle (venous return) increases. The increased EDV causes the right ventricle to contract more forcefully on the next beat, bringing the two sides back into balance.

Contractility

The second factor that influences stroke volume is myocardial contractility, the strength of contraction at any given preload. Substances that increase contractility are positive inotropic agents; those that decrease contractility are negative inotropic agents. Thus, for a constant preload, the stroke volume increases when a positive inotropic substance is present. Positive inotropic agents often promote Ca²⁺ inflow during cardiac action potentials, which strengthens the force of the next contraction. Stimulation of the sympathetic division of the autonomic nervous system (ANS), hormones such as epinephrine and norepinephrine, increased Ca²⁺ level in the interstitial fluid, and the drug digitalis all have positive inotropic effects. In contrast, inhibition of the sympathetic division of the ANS, anoxia, acidosis, some anesthetics, and increased K⁺ level in the interstitial fluid have negative inotropic effects. Calcium channel blockers are
drugs that can have a negative inotropic effect by reducing Ca\textsuperscript{2+} inflow, thereby decreasing the strength of the heartbeat.

### Afterload

Ejection of blood from the heart begins when pressure in the right ventricle exceeds the pressure in the pulmonary trunk (about 20 mmHg), and when the pressure in the left ventricle exceeds the pressure in the aorta (about 80 mmHg). At that point, the higher pressure in the ventricles causes blood to push the semilunar valves open. The pressure that must be overcome before a semilunar valve can open is termed the **afterload**. An increase in afterload causes stroke volume to decrease, so that more blood remains in the ventricles at the end of systole. Conditions that can increase afterload include hypertension (elevated blood pressure) and narrowing of arteries by atherosclerosis (see page 750).

---

#### Clinical Connection

**Congestive Heart Failure**

In **congestive heart failure (CHF)**, there is a loss of pumping efficiency by the heart. Causes of CHF include coronary artery disease (see page 600), congenital defects, long-term high blood pressure (which increases the afterload), myocardial infarctions (regions of dead heart tissue due to a previous heart attack), and valvular disorders. As the pump becomes less effective, more blood remains in the ventricles at the end of each cycle, and gradually the end-diastolic volume (preload) increases. Initially, increased preload may promote increased force of contraction (the Frank–Starling law of the heart), but as the preload increases further, the heart is overstretched and contracts less forcefully. The result is a potentially lethal positive feedback loop: Less-effective pumping leads to even lower pumping capability.

Often, one side of the heart starts to fail before the other. If the left ventricle fails first, it can’t pump out all the blood it receives. As a result, blood backs up in the lungs and causes **pulmonary edema**, fluid accumulation in the lungs that can cause suffocation if left untreated. If the right ventricle fails first, blood backs up in the systemic veins and, over time, the kidneys cause an increase in blood volume. In this case, the resulting ** peripheral edema** usually is most noticeable in the feet and ankles.

---

### Regulation of Heart Rate

As you have just learned, cardiac output depends on both heart rate and stroke volume. Adjustments in heart rate are important in the short-term control of cardiac output and blood pressure. The sinoatrial (SA) node initiates contraction and, if left to itself, would set a constant heart rate of about 100 beats/min. However, tissues require different volumes of blood flow under different conditions. During exercise, for example, cardiac output rises to supply working tissues with increased amounts of oxygen and nutrients. Stroke volume may fall if the ventricular myocardium is damaged or if blood volume is reduced by bleeding. In these cases, homeostatic mechanisms maintain adequate cardiac output by increasing the heart rate and contractility. Among the several factors that contribute to regulation of heart rate, the most important are the autonomic nervous system and hormones released by the adrenal medullae (epinephrine and norepinephrine).

#### Autonomic Regulation of Heart Rate

Nervous system regulation of the heart originates in the cardiovascular center in the medulla oblongata. This region of the brain stem receives input from a variety of sensory receptors and from higher brain centers, such as the limbic system and cerebral cortex. The cardiovascular center then directs appropriate output by increasing or decreasing the frequency of nerve impulses in both the sympathetic and parasympathetic branches of the ANS (Figure 20.16).

Even before physical activity begins, especially in competitive situations, heart rate may climb. This anticipatory increase occurs because the limbic system sends nerve impulses to the cardiovascular center in the medulla. As physical activity begins, **proprioceptors** that are monitoring the position of limbs and muscles send nerve impulses at an increased frequency to the cardiovascular center. Proprioceptor input is a major stimulus for the quick rise in heart rate that occurs at the onset of physical activity. Other sensory receptors that provide input to the cardiovascular center include **chemoreceptors**, which monitor chemical changes in the blood, and **baroreceptors**, which monitor the stretching of major arteries and veins caused by the pressure of the blood flowing through them. Important baroreceptors located in the arch of the aorta and in the carotid arteries (see Figure 21.13 on page 777) detect changes in blood pressure and provide input to the cardiovascular center when it changes. The role of baroreceptors in the regulation of blood pressure is discussed in detail in Chapter 21. Here we focus on the innervation of the heart by the sympathetic and parasympathetic branches of the ANS.

Sympathetic neurons extend from the medulla oblongata into the spinal cord. From the thoracic region of the spinal cord, sympathetic cardiac accelerator nerves extend out to the SA node, AV node, and most portions of the myocardium. Impulses in the cardiac accelerator nerves trigger the release of norepinephrine, which binds to beta-1 receptors on cardiac muscle fibers. This interaction has two separate effects: (1) In SA (and AV) node fibers, norepinephrine speeds the rate of spontaneous depolarization so that these pacemakers fire impulses more rapidly and heart rate increases; (2) in contractile fibers throughout the atria and ventricles, norepinephrine enhances Ca\textsuperscript{2+} entry through the voltage-gated slow Ca\textsuperscript{2+} channels, thereby increasing contractility. As a result, a greater volume of blood is ejected during systole. With a moderate increase in heart rate, stroke volume does not decline because the increased contractility offsets the decreased preload. With maximal sympathetic stimulation, however, heart rate may reach 200 beats/min in a 20-year-old person. At such a high heart rate, stroke volume is lower than at rest due to the very short filling time. The maximal heart rate declines with age; as a rule, subtracting your age from 220 provides a good estimate of your maximal heart rate in beats per minute.
Parasympathetic nerve impulses reach the heart via the right and left vagus (X) nerves. Vagal axons terminate in the SA node, AV node, and atrial myocardium. They release acetylcholine, which decreases heart rate by slowing the rate of spontaneous depolarization in autorhythmic fibers. As only a few vagal fibers innervate ventricular muscle, changes in parasympathetic activity have little effect on contractility of the ventricles.

A continually shifting balance exists between sympathetic and parasympathetic stimulation of the heart. At rest, parasympathetic stimulation predominates. The resting heart rate—about 75 beats/min—is usually lower than the autorhythmic rate of the SA node (about 100 beats/min). With maximal stimulation by the parasympathetic division, the heart can slow to 20 or 30 beats/min, or can even stop momentarily.

**Chemical Regulation of Heart Rate**

Certain chemicals influence both the basic physiology of cardiac muscle and the heart rate. For example, hypoxia (lowered oxygen level), acidosis (low pH), and alkalosis (high pH) all depress cardiac activity. Several hormones and cations have major effects on the heart:

1. **Hormones.** Epinephrine and norepinephrine (from the adrenal medullae) enhance the heart’s pumping effectiveness. These hormones affect cardiac muscle fibers in much the same way as does norepinephrine released by cardiac accelerator nerves—they increase both heart rate and contractility. Exercise, stress, and excitement cause the adrenal medullae to release more hormones. Thyroid hormones also enhance cardiac contractility and increase heart rate. One sign of hyperthyroidism (excessive thyroid hormone) is tachycardia, an elevated resting heart rate.

2. **Cations.** Given that differences between intracellular and extracellular concentrations of several cations (for example, Na⁺ and K⁺) are crucial for the production of action potentials in all nerve and muscle fibers, it is not surprising that ionic imbalances can quickly compromise the pumping effectiveness of the heart. In particular, the relative concentrations of three cations—K⁺, Ca²⁺, and Na⁺—have a large effect on cardiac function. Elevated blood levels of K⁺ or Na⁺ decrease heart rate and contractility. Excess Na⁺ blocks Ca²⁺ influx during cardiac action potentials, thereby decreasing the force of contraction, whereas excess K⁺ blocks generation of action potentials. A moderate increase in interstitial (and thus intracellular) Ca²⁺ level speeds heart rate and strengthens the heartbeat.

**Other Factors in Heart Rate Regulation**

Age, gender, physical fitness, and body temperature also influence resting heart rate. A newborn baby is likely to have a resting heart rate over 120 beats/min; the rate then gradually declines throughout life. Adult females often have slightly higher resting heart rates than adult males, although regular exercise tends to bring resting heart rate down in both sexes. A physically fit person may even exhibit bradycardia (brad-e-KAR-de-a; bradys- = slow), a resting heart rate under 50 beats/min. This is a beneficial effect of endurance-type training because a slowly beating heart is more energy efficient than one that beats more rapidly.

Increased body temperature, as occurs during a fever or strenuous exercise, causes the SA node to discharge impulses more quickly, thereby increasing heart rate. Decreased body temperature decreases heart rate and strength of contraction.

---

**Figure 20.16  Nervous system control of the heart.**

The cardiovascular center in the medulla oblongata controls both sympathetic and parasympathetic nerves that innervate the heart.

---

**INPUT TO CARDIOVASCULAR CENTER**
- From higher brain centers: cerebral cortex, limbic system, and hypothalamus
- From sensory receptors:
  - Proprioceptors—monitor movements
  - Chemoreceptors—monitor blood chemistry
  - Baroreceptors—monitor blood pressure

**OUTPUT TO HEART**
- Increased rate of spontaneous depolarization in SA node (and AV node) increases heart rate
- Increased contractility of atria and ventricles increases stroke volume
- Decreased rate of spontaneous depolarization in SA node (and AV node) decreases heart rate

---

What region of the heart is innervated by the sympathetic division but not by the parasympathetic division?
During surgical repair of certain heart abnormalities, it is helpful to slow a patient’s heart rate by hypothermia (hi̍-po̍-ther-mi̍-ə), in which the person’s body is deliberately cooled to a low core temperature. Hypothermia slows metabolism, which reduces the oxygen needs of the tissues, allowing the heart and brain to withstand short periods of interrupted or reduced blood flow during the procedure.

Figure 20.17 summarizes the factors that can increase stroke volume and heart rate to achieve an increase in cardiac output.

**Figure 20.17 Factors that increase cardiac output.**

Cardiac output equals stroke volume multiplied by heart rate.

- **Increased end diastolic volume (stretches the heart)**
  - Increased PRELOAD
  - Within limits, cardiac muscle fibers contract more forcefully with stretching (Frank-Starling law of the heart)

- **Positive inotropic agents such as increased sympathetic stimulation; catecholamines, glucagon, or thyroid hormones in the blood; increased Ca²⁺ in extracellular fluid**
  - Increased CONTRACTILITY
  - Positive inotropic agents increase force of contraction at all physiological levels of stretch

- **Decreased arterial blood pressure during diastole**
  - Decreased AFTERLOAD
  - Semilunar valves open sooner when blood pressure in aorta and pulmonary artery is lower

- **Increased sympathetic stimulation and decreased parasympathetic stimulation**
  - NERVOUS SYSTEM
    - Cardiovascular center in medulla oblongata receives input from cerebral cortex, limbic system, proprioceptors, baroreceptors, and chemoreceptors
  - Catecholamine or thyroid hormones in the blood; moderate increase in extracellular Ca²⁺
  - Infants and senior citizens, females, low physical fitness, increased body temperature

- **Increased cardiac reserve. How does it change with training or with heart failure?**

- **How do the sympathetic and parasympathetic divisions of the autonomic nervous system adjust heart rate?**

- **When you are exercising, contraction of skeletal muscles helps return blood to the heart more rapidly. Would this tend to increase or decrease stroke volume?**
EXERCISE AND THE HEART

OBJECTIVE
• Explain the relationship between exercise and the heart.

Regardless of current fitness level, a person's cardiovascular fitness can be improved at any age with regular exercise. Some types of exercise are more effective than others for improving the health of the cardiovascular system. Aerobics, any activity that works large body muscles for at least 20 minutes, elevates cardiac output and accelerates metabolic rate. Three to five such sessions a week are usually recommended for improving the health of the cardiovascular system. Brisk walking, running, bicycling, cross-country skiing, and swimming are examples of aerobic activities.

Sustained exercise increases the oxygen demand of the muscles. Whether the demand is met depends mainly on the adequacy of cardiac output and proper functioning of the respiratory system. After several weeks of training, a healthy person increases maximal cardiac output, thereby increasing the maximal rate of oxygen delivery to the tissues. Oxygen delivery also rises because skeletal muscles develop more capillary networks in response to long-term training.

During strenuous activity, a well-trained athlete can achieve a cardiac output double that of a sedentary person, in part because training causes hypertrophy (enlargement) of the heart. Even though the heart of a well-trained athlete is larger, resting cardiac output is about the same as in a healthy untrained person, because stroke volume is increased while heart rate is decreased. The resting heart rate of a trained athlete often is only 40–60 beats per minute (resting bradycardia). Regular exercise also helps to reduce blood pressure, anxiety, and depression; control weight; and increase the body's ability to dissolve blood clots by increasing fibrinolytic activity.

CHECKPOINT
24. What are some of the cardiovascular benefits of regular exercise?

HELP FOR FAILING HEARTS

OBJECTIVE
• Describe several techniques used for failing hearts.

As the heart fails, a person has decreasing ability to exercise or even to move around. A variety of surgical techniques and medical devices exist to aid a failing heart. For some patients, even a 10% increase in the volume of blood ejected from the ventricles can mean the difference between being bedridden and having limited mobility.

A cardiac (heart) transplant is the replacement of a severely damaged heart with a normal heart from a brain-dead or recently deceased donor. Cardiac transplants are performed on patients with end-stage heart failure or severe coronary artery disease. Once a suitable heart is located, the chest cavity is exposed through a midsternal cut. After the patient is placed on a heart-lung bypass machine, which oxygenates and circulates blood, the pericardium is cut to expose the heart. Next, the diseased heart is removed (usually except for the posterior wall of the left atrium) (Figure 20.18) and the donor heart is trimmed and sutured into position so that the remaining left atrium and great vessels are connected to the donor heart. The new heart is

Figure 20.18 Cardiac transplantation.
Cardiac transplantation is the replacement of a severely damaged heart with a normal heart from a brain-dead or recently deceased donor.
Which patients are candidates for cardiac transplantation?

started as blood flows through it (an electrical shock may be used to correct an abnormal rhythm), the patient is weaned from the heart-lung bypass machine, and the chest is closed. The patient must remain on immunosuppressant drugs for a lifetime to prevent rejection. Since the vagus (X) nerve is severed during the surgery, the new heart will beat at about 100 times per minute until nerve regrowth occurs.

Usually, a donor heart is perfused with a cold solution and then preserved in sterile ice. This can keep the heart viable for about 4–5 hours. In May 2007, surgeons in the United States performed the first beating-heart transplant. The donor heart was maintained at normal body temperature and hooked up to an organ care system that allowed it to keep beating with warm, oxygenated blood flowing through it. This greatly prolongs the time between removal of the heart from the donor and transplantation into a recipient and also decreases injury to the heart while being deprived of blood, which can lead to rejection. The safety and benefits of the oxygen care system are currently being evaluated.

Cardiac transplants are common today and produce good results, but the availability of donor hearts is very limited. Another approach is the use of cardiac assist devices and other surgical procedures that assist heart function without removing the heart. Table 20.1 describes several of these.

</tbody>
</table>
VADs are classified according to the ventricle that requires support. A left ventricular assist device (LVAD) helps the left ventricle pump blood into the aorta see (b). This is the most commonly used VAD. A right ventricular assist device (RVAD) helps the right ventricle to pump blood into the pulmonary trunk. A bi-ventricular assist device (BVAD) helps both the left and right ventricles perform their functions.

There are several VADs available, and which one is used depends on the specific needs of the patient. In order to help you understand how a VAD works, we will illustrate an LVAD to the right. An inflow tube attached to the apex of the left ventricle takes blood from the ventricle through a one-way valve into the pump unit. Once the pump fills with blood, an external control system triggers pumping and blood flows through a one-way valve into an outflow tube that delivers blood into the aorta. The external control system is on a belt around the waist or on a shoulder strap. Some VADs pump at a constant rate; others are coordinated with the person’s heartbeat.

**Cardiomyoplasty**
A large piece of the patient’s own skeletal muscle (left latissimus dorsi) is partially freed from its connective tissue attachments and wrapped around the heart, leaving the blood and nerve supply intact. An implanted pacemaker stimulates the skeletal muscle’s motor neurons to cause contraction 10–20 times per minute, in synchrony with some of the heartbeats.

**Skeletal muscle assist device**
A piece of the patient’s own skeletal muscle is used to fashion a pouch that is inserted between the heart and the aorta, functioning as a booster heart. A pacemaker stimulates the muscle’s motor neurons to elicit contraction.
DEVELOPMENT OF THE HEART

**OBJECTIVE**

- Describe the development of the heart.

Listening to a fetal heartbeat for the first time is an exciting moment for prospective parents, but it is also an important diagnostic tool. The cardiovascular system is one of the first systems to form in an embryo, and the heart is the first functional organ. This order of development is essential because of the need of the rapidly growing embryo to obtain oxygen and nutrients and get rid of wastes. As you will learn shortly, the development of the heart is a complex process, and any disruptions along the way can result in congenital (present at birth) disorders of the heart. Such disorders, described on page 752, are responsible for almost half of all deaths from birth defects.

The heart begins its development from mesoderm on day 18 or 19 following fertilization. In the head end of the embryo, the heart develops from a group of mesodermal cells called the cardiogenic area (kar-de-o-JEN-ik; cardi- = heart; -genic = producing) (Figure 20.19a). In response to signals from the underlying endoderm, the mesoderm in the cardiogenic area forms a pair of elongated strands called cardiogenic cords. Shortly after, these cords develop a hollow center and then become known as endocardial tubes (Figure 20.19b). With lateral folding of the...
embryo, the paired endocardial tubes approach each other and fuse into a single tube called the **primitive heart tube** on day 21 following fertilization (Figure 20.19c).

On the twenty-second day, the primitive heart tube develops into five distinct regions and begins to pump blood. From tail end to head end (and the direction of blood flow) they are the (1) **sinus venosus**, (2) **atrium**, (3) **ventricle**, (4) **bulbus cordis**, and (5) **truncus arteriosus**. The sinus venosus initially receives blood from all the veins in the embryo; contractions of the heart begin in this region and follow sequentially in the other regions. Thus, at this stage, the heart consists of a series of unpaired regions. The fates of the regions are as follows:

1. The sinus venosus develops into part of the **right atrium**, **coronary sinus**, and **sinoatrial (SA) node**.
2. The atrium develops into part of the **right atrium**, **right auricle**, and the **left atrium** and **left auricle**.
3. The ventricle gives rise to the **left ventricle**.
4. The bulbus cordis develops into the **right ventricle**.
5. The truncus arteriosus gives rise to the **ascending aorta** and **pulmonary trunk**.

On day 23, the primitive heart tube elongates. Because the bulbus cordis and ventricle grow more rapidly than other parts of the tube and because the atrial and venous ends of the tube are confined by the pericardium, the tube begins to loop and fold. At first, the primitive heart tube assumes a U-shape; later it becomes S-shaped (Figure 20.19e). As a result of these movements, which are completed by day 28, the atria and ventricles of the future heart are reoriented to assume their final adult positions. The remainder of heart development consists of reconstruction of the chambers and the formation of septa and valves to form a four-chambered heart.

On about day 28, thickenings of mesoderm of the inner lining of the heart wall, called **endocardial cushions**, appear (Figure 20.20). They grow toward each other, fuse, and divide the single **atrioventricular canal** (region between atria and ventricles) into smaller, separate left and right atrioventricular canals. Also, the **interatrial septum** begins its growth toward fused endocardial cushions. Ultimately, the interatrial septum and endocardial cushions unite and an opening in the septum, the **foramen ovale**, develops. The interatrial septum divides the atrial region into a **right atrium** and a **left atrium**. Before birth, the foramen ovale allows most blood entering the right atrium to pass into the left atrium. After birth, it normally closes so that the interatrial septum is a complete partition. The remnant of the foramen ovale is the fossa ovalis (Figure 20.20). Formation of the **interventricular septum** partitions the ventricular region into a **right ventricle** and a **left ventricle**. Partitioning of the atrioventricular canal, atrial region, and ventricular region is basically complete by the end of the fifth week. The **atrioventricular valves** form between the fifth and eighth weeks. The **semilunar valves** form between the fifth and ninth weeks.
Coronary Artery Disease

Coronary artery disease (CAD) is a serious medical problem that affects about 7 million people annually. Responsible for nearly three-quarters of a million deaths in the United States each year, it is the leading cause of death for both men and women. CAD results from the effects of the accumulation of atherosclerotic plaques (described shortly) in coronary arteries, which leads to a reduction in blood flow to the myocardium. Some individuals have no signs or symptoms; others experience angina pectoris (chest pain), and still others suffer heart attacks.

Risk Factors for CAD

People who possess combinations of certain risk factors are more likely to develop CAD. Risk factors (characteristics, symptoms, or signs present in a disease-free person that are statistically associated with a greater chance of developing a disease) include smoking, high blood pressure, diabetes, high cholesterol levels, obesity, “type A” personality, sedentary lifestyle, and a family history of CAD. Most of these can be modified by changing diet and other habits or can be controlled by taking medications. However, other risk factors are unmodifiable (beyond our control), including genetic predisposition (family history of CAD at an early age), age, and gender. For example, adult males are more likely than adult females to develop CAD; after age 70 the risks are roughly equal. Smoking is undoubtedly the number-one risk factor in all CAD-associated diseases, roughly doubling the risk of morbidity and mortality.

Development of Atherosclerotic Plaques

Although the following discussion applies to coronary arteries, the process can also occur in arteries outside the heart. Thickening of the walls of arteries and loss of elasticity are the main characteristics of arteriosclerosis (arter-Ô-skle-RO¯-sis; sclero- = hardening). One form of arteriosclerosis is atherosclerosis (ath-er-Ô-skle-RO¯-sis), a progressive disease characterized by the formation in the walls of large and medium-sized arteries of lesions called atherosclerotic plaques (Figure 20.21a,b).

To understand how atherosclerotic plaques develop, you will need to learn about the role of molecules produced by the liver and small intestine called lipoproteins. These spherical particles consist of an inner core of triglycerides and other lipids and an outer shell of proteins, phospholipids, and cholesterol. Like most lipids, cholesterol does not dissolve in water and must be made water-soluble in order to be transported in the blood. This is accomplished by combining it with lipoproteins. Two major lipoproteins are low-density lipoproteins (LDLs) and high-density lipoproteins (HDLs). LDLs transport cholesterol from the liver to body cells for use in cell membrane repair and the production of steroid hormones and bile salts. However, excessive amounts of LDLs promote atherosclerosis, so the cholesterol in these particles is commonly known as “bad cholesterol.” HDLs, on the other hand, remove excess cholesterol from body cells and transport it to the liver for elimination. Because HDLs decrease blood cholesterol level, the cholesterol in HDLs is commonly referred to as “good cholesterol.” Basically, you want your LDL concentration to be low and your HDL concentration to be high.

It has been learned recently that inflammation, a defensive response of the body to tissue damage, plays a key role in the development of atherosclerotic plaques. As a result of tissue damage, blood vessels dilate and increase their permeability, and phagocytes, including macrophages, appear in large numbers. The formation of atherosclerotic plaques begins when excess LDLs from the blood accumulate in the inner layer of an artery wall (layer closest to the bloodstream) and the lipids and proteins in the LDLs undergo oxidation and the proteins also bind to sugars. In response, endothelial and smooth muscle cells of the artery secrete substances that attract monocytes from the blood and convert them into macrophages. The macrophages then ingest and become so filled with oxidized LDL particles that they have a foamy appearance when viewed microscopically (foam cells). T cells (lymphocytes) follow monocytes into the inner lining of an artery where they release chemicals that intensify the inflammatory response. Together, the foam cells, macrophages, and T cells form a fatty streak, the beginning of an atherosclerotic plaque.

Macrophages secrete chemicals that cause smooth muscle cells of the middle layer of an artery to migrate to the top of the atherosclerotic plaque, forming a cap over it and thus walling it off from the blood.
Because most atherosclerotic plaques expand away from the bloodstream rather than into it, blood can still flow through the affected artery with relative ease, often for decades. Relatively few heart attacks occur when plaque in a coronary artery expands into the bloodstream and restricts blood flow. Most heart attacks occur when the cap over the plaque breaks open in response to chemicals produced by foam cells. In addition, T cells induce foam cells to produce tissue factor (TF), a chemical that begins the cascade of reactions that result in blood clot formation. If the clot in a coronary artery is large enough, it can significantly decrease or stop the flow of blood and result in a heart attack.

In recent years, a number of new risk factors (all modifiable) have been identified as significant predictors of CAD. **C-reactive proteins (CRPs)** are proteins produced by the liver or present in blood in an inactive form that are converted to an active form during inflammation. CRPs may play a direct role in the development of atherosclerosis by promoting the uptake of LDLs by macrophages. **Lipoprotein (a)** is an LDL-like particle that binds to endothelial cells, macrophages, and blood platelets, may promote the proliferation of smooth muscle fibers, and inhibits the breakdown of blood clots. **Fibrinogen** is a glycoprotein involved in blood clotting that may help regulate cellular proliferation, vasoconstriction, and platelet aggregation. **Homocysteine** is an amino acid that may induce blood vessel damage by promoting platelet aggregation and smooth muscle fiber proliferation.

**Diagnosis of CAD**

Many procedures may be employed to diagnose CAD; the specific procedure used will depend on the signs and symptoms of the individual.

A resting electrocardiogram (see page 735) is the standard test employed to diagnose CAD. **Stress testing** can also be performed. In an **exercise stress test**, the functioning of the heart is monitored when placed under physical stress by exercising using a treadmill, an exercise bicycle, or arm exercises. During the procedure, ECG recordings are monitored continuously and blood pressure is monitored at intervals. A **nonexercise (pharmacologic) stress test** is used for individuals who cannot exercise due to conditions such as arthritis. A medication is injected that stresses the heart to mimic the effects of exercise. During both exercise and nonexercise stress testing, **radionuclide imaging** may be performed to evaluate blood flow through heart muscle (see page 23).

Diagnosis of CAD may also involve **echocardiography** (ek’-ó-kar-de-OG-ra-fe), a technique that uses ultrasound waves to image the interior of the heart. Echocardiography allows the heart to be seen in motion and can be used to determine the size, shape, and functions of the chambers of the heart; the volume and velocity of blood pumped from the heart; the status of heart valves; the presence of birth defects; and abnormalities of the pericardium. A fairly recent technique for evaluating CAD is **electron beam computerized tomography (EBCT)**, which detects calcium deposits in coronary arteries. These calcium deposits are indicators of atherosclerosis.

**Cardiac catheterization** (kath’-é-ter-i-ZA-shun) is an invasive procedure used to visualize the heart’s chambers, valves, and great vessels in order to diagnose and treat disease not related to abnormalities of the coronary arteries. It may also be used to measure pressure in the heart and great vessels; to assess cardiac output; to measure the flow of blood through the heart and great vessels; to identify the location of septal and valvar defects; and to take tissue and blood samples. The basic procedure involves inserting a long, flexible, radiopaque catheter (plastic tube) into a peripheral vein (for **right heart catheterization**) or a peripheral artery (for **left heart catheterization**) and guiding it under fluoroscopy (x-ray observation).

**Coronary angiography** (an’-jé-OG-ra-fe; angio- = blood vessel; grapho = to write) is an invasive procedure used to obtain information about the coronary arteries. In the procedure, a catheter is inserted into an artery in the groin or wrist and threaded under fluoroscopy toward the heart and then into the coronary arteries. After the tip of the catheter is in place, a radiopaque contrast medium is injected into the coronary arteries. The radiographs of the arteries, called **angiograms**, appear in motion on a monitor and the information is recorded on a videotape or computer disc. Coronary angiography may be used to visualize coronary arteries (see page 22) and inject clot-dissolving drugs, such as streptokinase or tissue plasminogen activator (t-PA), into a coronary artery to dissolve an obstructing thrombus.

**Treatment of CAD**

Treatment options for CAD include drugs (antihypertensives, nitroglycerine, beta blockers, cholesterol-lowering drugs, and clot-dissolving agents) and various surgical and nonsurgical procedures designed to increase the blood supply to the heart.

**Coronary artery bypass grafting (CABG)** is a surgical procedure in which a blood vessel from another part of the body is attached (“grafted”) to a coronary artery to bypass an area of blockage. A piece of the grafted blood vessel is sutured between the aorta and the unblocked portion of the coronary artery (Figure 20.22a).

A nonsurgical procedure used to treat CAD is **percutaneous transluminal coronary angioplasty (PTCA)** (percutaneous = through the skin; trans- = across; lumen = an opening or channel in a tube; angio- = blood vessel; -plasty = to mold or to shape). In one variation of this procedure, a balloon catheter is inserted into an artery of an arm or
leg and gently guided into a coronary artery (Figure 20.22b). While dye is released, angiograms (x-rays of blood vessels) are taken to locate the plaques. Next, the catheter is advanced to the point of obstruction, and a balloonlike device is inflated with air to squash the plaque against the blood vessel wall. Because 30–50% of PTCA-opened arteries fail due to restenosis (renarrowing) within six months after the procedure is done, a stent may be inserted via a catheter. A stent is a metallic, fine wire tube that is permanently placed in an artery to keep the artery patent (open), permitting blood to circulate (Figure 20.22c, d). Restenosis may be due to damage from the procedure itself, for PTCA may damage the arterial wall, leading to platelet activation, proliferation of smooth muscle fibers, and plaque formation. Recently, drug-coated (drug-eluting) coronary stents have been used to prevent restenosis. The stents are coated with one of several antiproliferative drugs (drugs that inhibit the proliferation of smooth muscle fibers of the middle layer of an artery) and anti-inflammatory drugs. It has been shown that drug-coated stents reduce the rate of restenosis when compared to bare-metal (noncoated) stents. In addition to balloon and stent angioplasty, laser-emitting catheters are used to vaporize plaques (excimer laser coronary angioplasty or ELCA) and small blades inside catheters are used to remove part of the plaque (directional coronary atherectomy).

One area of current research involves cooling the body's core temperature during procedures such as coronary artery bypass grafting (CABG). There have been some promising results from the application of cold therapy during a cerebral vascular accident (CVA or stroke). This research stemmed from observations of people who had suffered a hypothermic incident (such as cold-water drowning) and recovered with relatively minimal neurologic deficits.

**Congenital Heart Defects**

A defect that is present at birth, and usually before, is called a congenital defect. Many such defects are not serious and may go unnoticed for a lifetime. Others are life threatening and must be surgically repaired. Among the several congenital defects that affect the heart are the following (Figure 20.23):

- **Coarctation** (kō'-ark-TA-shun) of the aorta. In this condition, a segment of the aorta is too narrow, and thus the flow of oxygenated blood to the body is reduced, the left ventricle is forced to pump harder, and high blood pressure develops. Coarctation is usually repaired surgically by removing the area of obstruction. Surgical interventions that are done in childhood may require revisions in adulthood. Another surgical procedure is balloon dilation, insertion and inflation of a device in the aorta to stretch the vessel. A stent can be inserted and left in place to hold the vessel open.

- **Patent ductus arteriosus (PDA).** In some babies, the ductus arteriosus, a temporary blood vessel between the aorta and the pulmonary trunk, remains open rather than closing shortly after birth. As a result, aortic blood flows into the lower-pressure pulmonary trunk, thus increasing the pulmonary trunk blood pressure and overworking both ventricles. In uncomplicated PDA, medication can be used to facilitate the closure of the defect. In more severe cases, surgical intervention may be required.

- **Septal defect.** A septal defect is an opening in the septum that separates the interior of the heart into left and right sides. In an atrial septal defect the fetal foramen ovale between the two atria fails to close after birth. A ventricular septal defect is caused by incomplete development of the interventricular septum. In such cases, oxygenated blood flows directly from the left ventricle into
figure 20.23 congenital heart defects.

- coarctation of the aorta
- patent ductus arteriosus
- atrial septal defect
- ventricular septal defect
- tetralogy of fallot

which four developmental defects occur in tetralogy of fallot?

the right ventricle, where it mixes with deoxygenated blood. The condition is treated surgically.

- tetralogy of fallot (tet-RAL-øj of fal-ô). this condition is a combination of four developmental defects: an interventricular septal defect, an aorta that emerges from both ventricles instead of from the left ventricle only, a stenosed pulmonary valve, and an enlarged right ventricle. there is a decreased flow of blood to the lungs and mixing of blood from both sides of the heart. this causes cyanosis, the bluish discoloration most easily seen in nail beds and mucous membranes when the level of deoxygenated hemoglobin is high; in infants, this condition is referred to as “blue baby.” despite the apparent complexity of this condition, surgical repair is usually successful.

arrhythmias

the usual rhythm of heartbeats, established by the SA node, is called normal sinus rhythm. the term arrhythmia (a-RITH-mé-a) or dysrhythmia refers to an abnormal rhythm as a result of a defect in the conduction system of the heart. the heart may beat irregularly, too quickly, or too slowly. symptoms include chest pain, shortness of breath, lightheadedness, dizziness, and fainting. arrhythmias may be caused by factors that stimulate the heart such as stress, caffeine, alcohol, nicotine, cocaine, and certain drugs that contain caffeine or other stimulants. arrhythmias may also be caused by a congenital defect, coronary artery disease, myocardial infarction, hypertension, defective heart valves, rheumatic heart disease, hyperthyroidism, and potassium deficiency.

arrhythmias are categorized by their speed, rhythm, and origination of the problem. bradycardia (bräd-e-KAR-dé-a; brady- = slow) refers to a slow heart rate (below 50 beats per minute); tachycardia (tak-i-KAR-dé-a; tachy- = quick) refers to a rapid heart rate (over 100 beats per minute); and fibrillation (fi-bri-LA-shun) refers to rapid, uncoordinated heartbeats. arrhythmias that begin in the atria are called supraventricular or atrial arrhythmias; those that originate in the ventricles are called ventricular arrhythmias.

- supraventricular tachycardia (SVT) is a rapid but regular heart rate (160–200 beats per minute) that originates in the atria. the episodes begin and end suddenly and may last from a few minutes to many hours. SVTs can sometimes be stopped by maneuvers that stimulate the vagus (X) nerve and decrease heart rate. these include straining as if having a difficult bowel movement, rubbing the area over the carotid artery in the neck to stimulate the carotid sinus (not recommended for people over 50 since it may cause a stroke), and plunging the face into a bowl of ice-cold water. treatment may also involve antiarrhythmic drugs and destruction of the abnormal pathway by radiofrequency ablation.
Heart block is an arrhythmia that occurs when the electrical pathways between the atria and ventricles are blocked, slowing the transmission of nerve impulses. The most common site of blockage is the atrioventricular node, a condition called atrioventricular (AV) block. In first-degree AV block, the P-Q interval is prolonged, usually because conduction through the AV node is slower than normal (Figure 20.24b). In second-degree AV block, some of the action potentials from the SA node are not conducted through the AV node. The result is “dropped” beats because excitation doesn’t always reach the ventricles. Consequently, there are fewer QRS complexes than P waves on the ECG. In third-degree (complete) AV block, no SA node action potentials get through the AV node. Autorhythmic fibers in the atria and ventricles pace the upper and lower chambers separately. With complete AV block, the ventricular contraction rate is less than 40 beats/min.

Atrial premature contraction (APC) is a heartbeat that occurs earlier than expected and briefly interrupts the normal heart rhythm. It often causes a sensation of a skipped heartbeat followed by a more forceful heartbeat. APCs originate in the atrial myocardium and are common in healthy individuals.

Atrial flutter consists of rapid, regular atrial contractions (240–360 beats/min) accompanied by an atrioventricular (AV) block in which some of the nerve impulses from the SA node are not conducted through the AV node.

Atrial fibrillation (AF) is a common arrhythmia, affecting mostly older adults, in which contraction of the atrial fibers is asynchronous (not in unison) so that atrial pumping ceases altogether. The atria may beat 300–600 beats/min. The ventricles may also speed up, resulting in a rapid heartbeat (up to 160 beats/min). The ECG of an individual with atrial fibrillation typically has no clearly defined P waves and irregularly spaced QRS complexes (and P-R intervals) (Figure 20.24c). Since the atria and ventricles do not beat in rhythm, the heartbeat is irregular in timing and strength. In an otherwise strong heart, atrial fibrillation reduces the pumping effectiveness of the heart by 20–30%. The most dangerous complication of atrial fibrillation is stroke since blood may stagnate in the atria and form blood clots. A stroke occurs when part of a blood clot occludes an artery supplying the brain.

Ventricular premature contraction. Another form of arrhythmia arises when an ectopic focus (ek-TOP-ik), a region of the heart other than the conduction system, becomes more excitable than

Figure 20.24 Representative arrhythmias.

(a) Normal electrocardiogram (ECG)

(c) Atrial fibrillation

(d) Ventricular tachycardia

(e) Ventricular fibrillation

Why is ventricular fibrillation such a serious arrhythmia?
normal and causes an occasional abnormal action potential to occur. As a wave of depolarization spreads outward from the ectopic focus, it causes a ventricular premature contraction (beat). The contraction occurs early in diastole before the SA node is normally scheduled to discharge its action potential. Ventricular premature contractions may be relatively benign and may be caused by emotional stress, excessive intake of stimulants such as caffeine, alcohol, or nicotine, and lack of sleep. In other cases, the premature beats may reflect an underlying pathology.

- **Ventricular tachycardia (VT or V-tach)** is an arrhythmia that originates in the ventricles and is characterized by 4 or more ventricular premature contractions. It causes the ventricles to beat too fast (at least 120 beats/min) (Figure 20.24d). VT is almost always associated with heart disease or a recent myocardial infarction and may develop into a very serious arrhythmia called ventricular fibrillation (described shortly). Sustained VT is dangerous because the ventricles do not fill properly and thus do not pump sufficient blood. The result may be low blood pressure and heart failure.

- **Ventricular fibrillation (VF or V-fib)** is the most deadly arrhythmia, in which contractions of the ventricular fibers are completely asynchronous so that the ventricles quiver rather than contract in a coordinated way. As a result, ventricular pumping stops, blood ejection ceases, and circulatory failure and death occur unless there is immediate medical intervention. During ventricular fibrillation, the ECG has no clearly defined P waves, QRS complexes, or T waves (Figure 20.24e). The most common cause of ventricular fibrillation is inadequate blood flow to the heart due to coronary artery disease, as occurs during a myocardial infarction. Other causes are cardiovascular shock, electrical shock, drowning, and very low potassium levels. Ventricular fibrillation causes unconsciousness in seconds and, if untreated, seizures occur and irreversible brain damage may occur after five minutes. Death soon follows. Treatment involves cardiopulmonary resuscitation (CPR) and defibrillation. In defibrillation (dé-fib-re-LÁ-shun), also called cardioversion (kar'-dé-ö-VER-shun), a strong, brief electrical current is passed to the heart and often can stop the ventricular fibrillation. The electrical shock is generated by a device called a defibrillator (dé-FIB-ri-lá-tor) and applied via two large paddle-shaped electrodes pressed against the skin of the chest. Patients who face a high risk of dying from heart rhythm disorders now can receive an automatic implantable cardioverter defibrillator (AICD), an implanted device that monitors their heart rhythm and delivers a small shock directly to the heart when a life-threatening rhythm disturbance occurs. Thousands of patients around the world have AICDs, including Dick Cheney, Vice President of the United States, who received a combination pacemaker-defibrillator in 2001. Also available are automated external defibrillators (AEDs) that function like AICDs, except that they are external devices. About the size of a laptop computer, AEDs are used by emergency response teams and are found increasingly in public places such as stadiums, casinos, airports, hotels, and shopping malls. Defibrillation may also be used as an emergency treatment for cardiac arrest.

**MEDICAL TERMINOLOGY**

**Asystole** (a-SISt-o-lé; a- = without) Failure of the myocardium to contract.

**Cardiac arrest** (KAR-dé-ak a-REST) A clinical term meaning cessation of an effective heartbeat. The heart may be completely stopped or in ventricular fibrillation.

**Cardiomegaly** (kar'-dé-ö-MEG-a-lé; mega = large) Heart enlargement.

**Cardiac rehabilitation** (kar'-dé-ö-reh-BIL-a-shun) A supervised program of progressive exercise, psychological support, education, and training to enable a patient to resume normal activities following a myocardial infarction.

**Cardiomyopathy** (kar'-dé-ö-mi-O-pathé; myo- = muscle; -pathos = disease) A progressive disorder in which ventricular structure or function is impaired. In dilated cardiomyopathy, the ventricles enlarge (stretch) and become weaker and reduce the heart’s pumping action. In hypertrophic cardiomyopathy, the ventricular walls thicken and the pumping efficiency of the ventricles is reduced.

**Commotio cordis** (kó-MO-shé-Ö KOR-dis; commotio = disturbance; cordis = heart) Damage to the heart, frequently fatal, as a result of a sharp, nonpenetrating blow to the chest while the ventricles are repolarizing.

**Cor pulmonale (CP)** (kor pul-mön-ALÉ; cor- = heart; pulmon- = lung) A term referring to right ventricular hypertrophy from disorders that bring about hypertension (high blood pressure) in the pulmonary circulation.

**Ejection fraction** The fraction of the end-diastolic volume (EDV) that is ejected during an average heartbeat. Equal to stroke volume (SV) divided by EDV.

**Electrophysiological testing** (e-lek'-tro-fiz'-é-Ö-ji-kal) A procedure in which a catheter with an electrode is passed through blood vessels and introduced into the heart. It is used to detect the exact locations of abnormal electrical conduction pathways. Once an abnormal pathway is located, it can be destroyed by sending a current through the electrode, a procedure called radiofrequency ablation.

**Palpitation** (pal'-pi-TÄ-shun) A fluttering of the heart or an abnormal rate or rhythm of the heart about which an individual is aware.

**Paroxysmal tachycardia** (par'-ök-SIZ-mal tak'-e-KAR-dé-a; tachy- = quick) A period of rapid heartbeats that begins and ends suddenly.

**Sick sinus syndrome** An abnormally functioning SA node that initiates heartbeats too slowly or rapidly, pauses too long between heartbeats, or stops producing heartbeats. Symptoms include lightheadedness, shortness of breath, loss of consciousness, and palpitations. It is caused by degeneration of cells in the SA node and is common in elderly persons. It is also related to coronary artery disease. Treatment consists of drugs to speed up or slow down the heart or implantation of an artificial pacemaker.

**Sudden cardiac death** The unexpected cessation of circulation and breathing due to an underlying heart disease such as ischemia, myocardial infarction, or a disturbance in cardiac rhythm.
CHAPTER 20
Heart Valves and Circulation of Blood (p. 725)

The phases of an action potential in a ventricular contractile fiber include rapid depolarization, a long plateau, and repolarization.
6.

Cardiac muscle tissue has a long refractory period, which prevents
tetanus.
5.

The record of electrical changes during each cardiac cycle is called
7.

An electrocardiogram (ECG). A normal ECG consists of a P wave
7.

Cardiac muscle fibers are connected end-to-end via intercalated
discs. Desmosomes in the discs provide strength, and gap junctions
allow muscle action potentials to conduct from one muscle fiber to
its neighbors.
3.

Autorhythmic fibers form the conduction system, cardiac muscle
fibers that spontaneously depolarize and generate action potentials.
4.

Components of the conduction system are the sinoatrial (SA) node
(pacemaker), atrioventricular (AV) node, atrioventricular (AV)
bundle (bundle of His), bundle branches, and Purkinje fibers.
4.

The P-Q interval represents the conduction time from the begin-
ing of atrial excitation to the beginning of ventricular excitation.
The S-T segment represents the time when ventricular contractile
fibers are fully depolarized.
8.

The Cardiac Cycle (p. 738)

1. A cardiac cycle consists of the systole (contraction) and diastole
(relaxation) of both atria and ventricles. With an average heartbeat of 75 beats/min, a complete cardiac cycle requires 0.8 seconds.
1.

Cardiac Output (p. 741)

1. Cardiac output (CO) is the amount of blood ejected per minute by
the left ventricle into the aorta (or by the right ventricle into the pul-
monary trunk). It is calculated as follows: CO (mL/min) = stroke
volume (SV) in mL/beat × heart rate (HR) in beats per minute.
1.

Stroke volume (SV) is the amount of blood ejected by a ventricle
during each systole.
2.

Cardiac reserve is the difference between a person’s maximum car-
diac output and his or her cardiac output at rest.
3.

Stroke volume is related to preload (stretch on the heart before it
pulmonary arteries, pulmonary capillaries, and pulmonary veins,
which carry it back to the left atrium.
4.

The coronary circulation provides blood flow to the myocardium. The
main arteries of the coronary circulation are left and right coronary ar-
teries; the main veins are the cardiac veins and the coronary sinus.
4.
contracts), contractility (forcefulness of contraction), and afterload (pressure that must be exceeded before ventricular ejection can begin).

5. According to the Frank-Starling law of the heart, a greater preload (end-diastolic volume) stretching cardiac muscle fibers just before they contract increases their force of contraction until the stretching becomes excessive.

6. Nervous control of the cardiovascular system originates in the cardiovascular center of the medulla oblongata.

7. Sympathetic impulses increase heart rate and force of contraction; parasympathetic impulses decrease heart rate.

8. Heart rate is affected by hormones (epinephrine, norepinephrine, thyroid hormones), ions (Na⁺, K⁺, Ca²⁺), age, gender, physical fitness, and body temperature.

Exercise and the Heart (p. 745)

1. Sustained exercise increases oxygen demand on muscles.

2. Among the benefits of aerobic exercise are increased cardiac output, decreased blood pressure, weight control, and increased fibrinolytic activity.

Help for Failing Hearts (p. 745)

1. A cardiac (heart) transplant is the replacement of a severely damaged heart with a normal one.

2. Cardiac arrest devices and procedures include the intra-aortic balloon pump, ventricular arrest device, cardiomyoplasty, and a skeletal muscle arrest device.

Development of the Heart (p. 748)

1. The heart develops from mesoderm.

2. The endocardial tubes develop into the four-chambered heart and great vessels of the heart.

SELF-QUIZ QUESTIONS 757

Fill in the blanks in the following statements.

1. The chamber of the heart with the thickest myocardium is the _____.

2. The phase of heart contraction is called _____; the phase of relaxation is called _____.

Indicate whether the following statements are true or false.

3. In auscultation, the lubb represents closing of the semilunar valves and the dupp represents closing of the atrioventricular valves.

4. The Frank-Starling law of the heart equalizes the output of the right and left ventricles and keeps the same volume of blood flowing to both the systemic and pulmonary circulations.

Choose the best answer to the following questions.

5. Which of the following is the correct route of blood through the heart from the systemic circulation to the pulmonary circulation and back to the systemic circulation?
   (a) right atrium, tricuspid valve, right ventricle, pulmonary semilunar valve, left atrium, mitral valve, left ventricle, aortic semilunar valve
   (b) left atrium, tricuspid valve, left ventricle, pulmonary semilunar valve, right atrium, mitral valve, right ventricle, aortic semilunar valve
   (c) left atrium, pulmonary semilunar valve, right atrium, tricuspid valve, left ventricle, aortic semilunar valve, right ventricle, mitral valve
   (d) left ventricle, mitral valve, left atrium, pulmonary semilunar valve, right ventricle, tricuspid valve, right atrium, aortic semilunar valve
   (e) right atrium, mitral valve, right ventricle, pulmonary semilunar valve, left atrium, tricuspid valve, left ventricle, aortic semilunar valve

6. Which of the following represents the correct pathway for conduction of an action potential through the heart?
   (a) AV node, AV bundle, SA node, Purkinje fibers, bundle branches
   (b) AV node, bundle branches, AV bundle, SA node, Purkinje fibers
   (c) SA node, AV node, AV bundle, bundle branches, Purkinje fibers
   (d) SA node, AV bundle, bundle branches, AV node, Purkinje fibers
   (e) SA node, AV node, Purkinje fibers, bundle branches, AV bundle
12. Match the following:

   (a) indicates ventricular repolarization  
   (b) represents the time from the beginning of ventricular depolarization to the end of ventricular repolarization  
   (c) represents atrial depolarization  
   (d) represents the time when the ventricular contractile fibers are fully depolarized; occurs during the plateau phase of the action potential  
   (e) represents the onset of ventricular depolarization  
   (f) represents the conduction time from the beginning of atrial excitation to the beginning of ventricular excitation

13. Match the following:

   (a) major branch from the ascending aorta; passes inferior to the left auricle  
   (b) lies in the posterior interventricular sulcus; supplies the walls of the ventricles with oxygenated blood  
   (c) located in the coronary sulcus on the posterior surface of the heart; receives most of the deoxygenated blood from the myocardium  
   (d) lies in the coronary sulcus; supplies oxygenated blood to the walls of the right ventricle  
   (e) lies in the coronary sulcus; drains the right atrium and right ventricle  
   (f) major branch from the ascending aorta; lies inferior to the right auricle  
   (g) lies in the posterior interventricular sulcus; drains the right and left ventricles  
   (h) lies in the anterior interventricular sulcus; supplies oxygenated blood to the walls of both ventricles  
   (i) lies in the anterior interventricular sulcus; drains the walls of both ventricles and the left atrium  
   (j) lies in the coronary sulcus; supplies oxygenated blood to the walls of the left ventricle and left atrium  
   (k) drain the right ventricle and open directly into the right atrium  

14. Match the following:

   (a) collects oxygenated blood from the pulmonary circulation  
   (b) pumps deoxygenated blood to the lungs for oxygenation  
   (c) their contraction pulls on and tightens the chordae tendineae, preventing the valve cusps from everting  
   (d) cardiac muscle tissue  
   (e) increase blood-holding capacity of the atria  
   (f) tendonlike cords connected to the atrioventricular valve cusps which, along with the papillary muscles, prevent valve eversion  
   (g) the superficial dense irregular connective tissue covering of the heart  
   (h) outer layer of the serous pericardium; is fused to the fibrous pericardium  
   (i) endothelial cells lining the interior of the heart; are continuous with the endothelium of the blood vessels  
   (j) pumps oxygenated blood to all body cells, except the air sacs of the lungs  
   (k) prevents backflow of blood from the right ventricle into the right atrium  
   (l) collects deoxygenated blood from the systemic circulation  
   (m) left atrioventricular valve  
   (n) the remnant of the foramen ovale, an opening in the interatrial septum of the fetal heart  
   (o) blood vessels that pierce the heart muscle and supply blood to the cardiac muscle fibers  
   (p) grooves on the surface of the heart which delineate the external boundaries between the chambers  
   (q) prevent backflow of blood from the arteries into the ventricles  
   (r) the gap junction and desmosome connections between individual cardiac muscle fibers  
   (s) internal wall dividing the chambers of the heart  
   (t) separate the upper and lower heart chambers, preventing backflow of blood from the ventricles back into the atria  
   (u) inner visceral layer of the pericardium; adheres tightly to the surface of the heart  
   (v) ridges formed by raised bundles of cardiac muscle fibers
15. Match the following:

**CRITICAL THINKING QUESTIONS**

1. Gerald recently visited the dentist to have his teeth cleaned and checked. During the cleaning process, Gerald had some bleeding from his gums. A couple of days later, Gerald developed a fever, rapid heartbeat, sweating, and chills. He visited his family physician who detected a slight heart murmur. Gerald was given antibiotics and continued to have his heart monitored. How was Gerald’s dental visit related to his illness?

2. Unathletic Sylvia makes a resolution to begin an exercise program. She tells you that she wants to make her heart “beat as fast as it can” during exercise. Explain to her why that may not be a good idea.

3. Mr. Perkins is a large, 62-year-old man with a weakness for sweets and fried foods. His idea of exercise is walking to the kitchen for more potato chips to eat while he is watching sports on television. Lately, he’s been troubled by chest pains when he walks up stairs. His doctor told him to quit smoking and scheduled a cardiac angiography for next week. What is involved in performing this procedure? Why did the doctor order this test?

**ANSWERS TO FIGURE QUESTIONS**

20.12 An enlarged Q wave may indicate a myocardial infarction (heart attack).

20.13 Action potentials propagate most slowly through the AV node.

20.14 The amount of blood in each ventricle at the end of ventricular diastole—called the end-diastolic volume—is about 130 mL in a resting person.

20.15 The first heart sound (S1), or lub, is associated with closure of the atrioventricular valves.

20.16 The ventricular myocardium receives innervation from the sympathetic division only.

20.17 The skeletal muscle “pump” increases stroke volume by increasing preload (end-diastolic volume).

20.18 Individuals with end-stage heart failure or severe coronary artery disease are candidates for cardiac transplantation.

20.19 The heart begins to contract by the twenty-second day of gestation.

20.20 Partitioning of the heart is complete by the end of the fifth week.

20.21 HDL removes excess cholesterol from body cells and transports it to the liver for elimination.

20.22 Coronary angiography is used to visualize many blood vessels.

20.23 Tetralogy of Fallot involves an interventricular septal defect, an aorta that emerges from both ventricles, a stenosed pulmonary valve, and an enlarged right ventricle.

20.24 Ventricular fibrillation is such a serious arrhythmia because ventricular pumping stops, blood ejection ceases, and circulatory failure and death can occur without immediate medical intervention.

20.24 Ventricular fibrillation is such a serious arrhythmia because...
BLOOD VESSELS, HEMODYNAMICS, AND HOMEOSTASIS

Blood vessels contribute to homeostasis by providing the structures for the flow of blood to and from the heart and the exchange of nutrients and wastes in tissues. They also play an important role in adjusting the velocity and volume of blood flow.

The cardiovascular system contributes to homeostasis of other body systems by transporting and distributing blood throughout the body to deliver materials (such as oxygen, nutrients, and hormones) and carry away wastes. The structures involved in these important tasks are the blood vessels, which form a closed system of tubes that carries blood away from the heart, transports it to the tissues of the body, and then returns it to the heart. The left side of the heart pumps blood through an estimated 100,000 km (60,000 mi) of blood vessels. The right side of the heart pumps blood through the lungs, enabling blood to pick up oxygen and unload carbon dioxide. Chapters 19 and 20 described the composition and functions of blood and the structure and function of the heart. In this chapter, we focus on the structure and functions of the various types of blood vessels; on hemodynamics (he-mo-di-NAM-iks; hemo- = blood; dynamics = power), the forces involved in circulating blood throughout the body; and on the blood vessels that constitute the major circulatory routes.
STRUCTURE AND FUNCTION OF BLOOD VESSELS

OBJECTIVES

- Contrast the structure and function of arteries, arterioles, capillaries, venules, and veins.
- Outline the vessels through which the blood moves in its passage from the heart to the capillaries and back.
- Distinguish between pressure reservoirs and blood reservoirs.

The five main types of blood vessels are arteries, arterioles, capillaries, venules, and veins. Arteries (AR-ter-ez) carry blood away from the heart to other organs. Large, elastic arteries leave the heart and divide into medium-sized, muscular arteries that branch out into the various regions of the body. Medium-sized arteries then divide into small arteries, which in turn divide into still smaller arteries called arterioles (ar-TER-ee-ols). As the arterioles enter a tissue, they branch into numerous tiny vessels called capillaries (KAP-i-lar-ez = hairlike). The thin walls of capillaries allow the exchange of substances between the blood and body tissues. Groups of capillaries within a tissue reunite to form small veins called venules (VEN-u-ols). These in turn merge to form progressively larger blood vessels called veins. Veins (VANZ) are the blood vessels that convey blood from the tissues back to the heart.

CLINICAL CONNECTION Angiogenesis and Disease

Angiogenesis (an-jé-oh-JEN-e-sis; angio- = blood vessel; -genesis = production) refers to the growth of new blood vessels. It is an important process in embryonic and fetal development, and in postnatal life serves important functions such as wound healing, formation of new uterine lining after menstruation, formation of the corpus luteum after ovulation, and development of blood vessels around obstructed arteries in the coronary circulation. Several proteins (peptides) are known to promote and inhibit angiogenesis.

Clinically angiogenesis is important because cells of a malignant tumor secrete proteins called tumor angiogenesis factors (TAFs) that stimulate blood vessel growth to provide nourishment for the tumor cells. Scientists are seeking chemicals that would inhibit angiogenesis and thus stop the growth of tumors. In diabetic retinopathy, angiogenesis may be important in the development of blood vessels that actually cause blindness, so finding inhibitors of angiogenesis may also prevent the blindness associated with diabetes.

Basic Structure of a Blood Vessel

The wall of a blood vessel consists of three layers, or tunics, of different tissues: an epithelial inner lining, a middle layer consisting of a smooth muscle and elastic connective tissue, and a connective tissue outer covering. The three structural layers of a generalized blood vessel from innermost to outermost are the tunica interna (intima), tunica media, and tunica externa (Figure 21.1). Modifications of this basic design account for the five types of blood vessels and the structural and functional differences among the various vessel types. Always remember that structural variations correlate to the differences in function that occur throughout the cardiovascular system.

Tunica Interna (Intima)
The tunica interna (intima) (tunic = garment; interna or intima = innermost) forms the inner lining of a blood vessel and is in direct contact with the blood as it flows through the lumen, or interior opening, of the vessel (Figure 21.1a, b). Although this layer has multiple parts, these tissue components contribute minimally to the thickness of the vessel wall. Its innermost layer is a simple squamous epithelium, called endothelium, which is continuous with the endocardial lining of the heart. The endothelium is a thin layer of flattened cells that lines the inner surface of the entire cardiovascular system (heart and blood vessels). Until recently, endothelial cells were regarded as little more than a passive barrier between the blood and the remainder of the vessel wall. It is now known that endothelial cells are active participants in a variety of vessel-related activities, including physically influencing blood flow, secreting locally acting chemical mediators that influence the contractile state of the vessel’s overlying smooth muscle, and assisting with capillary permeability.

The second component of the tunica interna is a basement membrane deep to the endothelium. It provides a physical support base for the epithelial layer. Its framework of collagen fibers affords the basal lamina significant tensile strength, yet its properties also provide resilience for stretching and recoil. The basal lamina anchors the endothelium to the underlying connective tissue while also regulating molecular movement. It appears to play an important role in guiding cell movements during tissue repair of blood vessel walls. The outermost part of the tunica interna, which forms the boundary between the tunica interna and tunica media, is the internal elastic lamina (lamina = thin plate). The internal elastic lamina is a thin sheet of elastic fibers with a variable number of window-like openings that give it the look of Swiss cheese. These openings facilitate diffusion of materials through the tunica interna to the thicker tunica media.

Tunica Media

The tunica media (media = middle) is a muscular and connective tissue layer that displays the greatest variation among the different vessel types (Figure 21.1a, b). In most vessels, it is a relatively thick layer comprised mainly of smooth muscle cells and substantial amounts of elastic fibers. The primary role of the smooth muscle cells, which extend circularly around the lumen like a ring encircles your finger, is to regulate the diameter of the lumen. As you will learn in more detail shortly, the rate of blood flow through different parts of the body is regulated by the extent of smooth muscle contraction in the walls of particular vessels. Furthermore, the extent of smooth muscle contraction in particular vessel types is crucial in the regulation of blood pressure.

In addition to regulating blood flow and blood pressure, smooth muscle contracts when vessels are damaged to help limit loss of blood through the injured vessel, and smooth muscle cells help
Figure 21.1 Comparative structure of blood vessels. The capillary in (c) is enlarged relative to the structures shown in parts (a) and (b).

Arteries carry blood from the heart to tissues; veins carry blood from tissues to the heart.

Q: Which vessel—the femoral artery or the femoral vein—has a thicker wall? Which has a wider lumen?
produce the elastic fibers within the tunica media that allow the vessels to stretch and recoil under the applied pressure of the blood.

The tunica media is the most variable of the tunics. As you study the different types of blood vessels in the remainder of this chapter, you will see that the structural differences in this layer account for the many variations in function among the different vessel types.

**Tunica Externa**

The outer covering of a blood vessel, the tunica externa (ex- = outermost), consists of elastic and collagen fibers (Figure 21.1a, b). Separating the tunica externa from the tunica media is a network of elastic fibers, the external elastic lamina which is part of the tunica media. The tunica externa contains numerous nerves and, especially in larger vessels, tiny blood vessels that supply the tissue of the vessel wall. These small vessels that supply blood to the tissues of the vessel are called vasa vasorum (vas = vessel), or vessels to the vessels. They are easily seen on large vessels such as the aorta. In addition to the important role of supplying the vessel wall with nerves and self-vessels, the tunica externa helps anchor the vessels to surrounding tissues.

**Arteries**

Because arteries (ar- = air; ter- = to carry) were found empty at death, in ancient times they were thought to contain only air. The wall of an artery has the three layers of a typical blood vessel, but has a thick muscular-to-elastic tunica media (Figure 21.1a). Due to their plentiful elastic fibers, arteries normally have high compliance, which means that their walls stretch easily or expand without tearing in response to a small increase in pressure.

Sympathetic fibers of the autonomic nervous system innervate the smooth muscle of blood vessels. An increase in sympathetic stimulation typically stimulates the smooth muscle to contract, squeezing the vessel wall and narrowing the lumen. Such a decrease in the diameter of the lumen of a blood vessel is called vasoconstriction. In contrast, when sympathetic stimulation decreases, or in the presence of certain chemicals (such as nitric oxide, $\text{H}^+$, and lactic acid), smooth muscle fibers relax. The resulting increase in lumen diameter is called vasodilation. Additionally, when an artery or arteriole is damaged, its smooth muscle contracts, producing vascular spasm of the vessel. Such a vasospasm limits blood flow through the damaged vessel and helps reduce blood loss if the vessel is small.

**Elastic Arteries**

Elastic arteries are the largest arteries in the body, ranging from the garden hose–sized aorta and pulmonary trunk to the finger-sized branches of the aorta. They have the largest diameter among arteries, but their vessel walls (approximately one-tenth of the vessel’s total diameter) are relatively thin compared to the overall size of the vessel. These vessels are characterized by well-defined internal and external elastic laminae, along with a thick tunica media that is dominated by elastic fibers, called the elastic lamellae (lamellae = little plate). Elastic arteries include the two major trunks that exit the heart (the aorta and the pulmonary trunk), along with the aorta’s major initial branches, such as the brachiocephalic, subclavian, common carotid, and common iliac arteries (see Figure 21.19a). Elastic arteries perform an important function: They help propel blood onward while the ventricles are relaxing. As blood is ejected from the heart into elastic arteries, their walls stretch, easily accommodating the surge of blood. As they stretch, the elastic fibers momentarily store mechanical energy, functioning as a pressure reservoir (Figure 21.2a). Then, the elastic fibers recoil and convert stored (potential) energy in the vessel into kinetic energy of the blood. Thus, blood continues to move through the arteries even while the ventricles are relaxed (Figure 21.2b). Because they conduct blood from the heart to medium-sized, more muscular arteries, elastic arteries also are called conducting arteries.

**Figure 21.2 Pressure reservoir function of elastic arteries.**

Recoil of elastic arteries keeps blood flowing during ventricular relaxation (diastole).

In atherosclerosis, the walls of elastic arteries become less compliant (stiffer). What effect does reduced compliance have on the pressure reservoir function of arteries?
CHAPTER 21

Muscular Arteries

Medium-sized arteries are called muscular arteries because their tunica media contains more smooth muscle and fewer elastic fibers than elastic arteries. The large amount of smooth muscle, approximately three-quarters of the total mass, makes the walls of muscular arteries relatively thick. Thus, muscular arteries are capable of greater vasoconstriction and vasodilation to adjust the rate of blood flow. Muscular arteries have a well-defined internal elastic lamina but a thin external elastic lamina. These two elastic laminae form the inner and outer boundaries of the muscular tunica media. In large arteries, the thick tunica media can have as many as 40 layers of circumferentially arranged smooth muscle cells; in smaller arteries there are as few as three layers.

Muscular arteries span a range of sizes from the pencil-sized femoral and axillary arteries to string-sized arteries that enter organs, measuring as little as 0.5 mm in diameter. Compared to elastic arteries, the vessel wall of muscular arteries comprises a larger percentage (25%) of the total vessel diameter. Because the muscular arteries continue to branch and ultimately distribute blood to each of the various organs, they are called distributing arteries. Examples include the brachial artery in the arm and radial artery in the forearm (see Figure 21.19a).

The tunica externa is often thicker than the tunica media in muscular arteries. This outer layer contains fibroblasts, collagen fibers, and elastic fibers all oriented longitudinally. The loose structure of this layer permits changes in the diameter of the vessel to take place but also prevents shortening or retraction of the vessel when it is cut.

Because of the reduced amount of elastic tissue in the walls of muscular arteries, these vessels do not have the ability to recoil and help propel the blood like the elastic arteries. Instead, the thick, muscular tunica media is primarily responsible for the functions of the muscular arteries. The ability of the muscle to contract and maintain a state of partial contraction is referred to as vascular tone. Vascular tone stiffens the vessel wall and is important in maintaining vessel pressure and efficient blood flow.

Anastomoses

Most tissues of the body receive blood from more than one artery. The union of the branches of two or more arteries supplying the same body region is called an anastomosis (a-nas-tó-MÖ-sis = connecting; plural is anastomoses) (see Figure 21.21b). Anastomoses between arteries provide alternative routes for blood to reach a tissue or organ. If blood flow stops for a short time when normal movements compress a vessel, or if a vessel is blocked by disease, injury, or surgery, then circulation to a part of the body is not necessarily stopped. The alternative route of blood flow to a body part through an anastomosis is known as collateral circulation. Anastomoses may also occur between veins and between arterioles and venules. Arteries that do not anastomose are known as end arteries. Obstruction of an end artery interrupts the blood supply to a whole segment of an organ, producing necrosis (death) of that segment. Alternative blood routes may also be provided by nonanastomosing vessels that supply the same region of the body.

Arterioles

Literally meaning small arteries, arterioles are abundant microscopic vessels that regulate the flow of blood into the capillary networks of the body’s tissues (see Figure 21.3). The approximately 400 million arterioles have diameters that range in size from 15 μm to 300 μm. The wall thickness of arterioles is one-half of the total vessel diameter.

Arterioles have a thin tunica interna with a thin, fenestrated (with small pores) internal elastic lamina that disappears at the terminal end. The tunica media consists of one to two layers of smooth muscle cells having a circular orientation in the vessel wall. The terminal end of the arteriole, the region called the metarteriole (meta = after), tapers toward the capillary junction. At the metarteriole-capillary junction, the distal-most muscle cell forms the precapillary sphincter (= to bind tight), which monitors the blood flow into the capillary; the other muscle cells in the arteriole regulate the resistance (opposition) to blood flow (see Figure 21.3).

The tunica externa of the arteriole consists of loose connective tissue containing abundant unmyelinated sympathetic nerves. This sympathetic nerve supply, along with the actions of local chemical mediators, can alter the diameter of arterioles and thus vary the rate of blood flow and resistance through these vessels.

Arterioles play a key role in regulating blood flow from arteries into capillaries by regulating resistance, the opposition to blood flow. Because of this they are known as resistance vessels. In a blood vessel, resistance is due mainly to friction between blood and the inner walls of blood vessels. When the blood vessel diameter is smaller, the friction is greater, so there is more resistance. Contraction of the smooth muscle of an arteriole causes vasoconstriction, which increases resistance even more and decreases blood flow into capillaries supplied by that arteriole. By contrast, relaxation of the smooth muscle of an arteriole causes vasodilation, which decreases resistance and increases blood flow into capillaries. A change in arteriole diameter can also affect blood pressure: Vasoconstriction of arterioles increases blood pressure, and vasodilation of arterioles decreases blood pressure.

Capillaries

Capillaries (capillus = little hair), the smallest of blood vessels, have diameters of 5–10 μm, and form the “U-turns” that connect the arterial outflow to the venous return (Figure 21.3). Since red blood cells have a diameter of 8 μm, they must often fold upon themselves in order to pass single file through the lumens of these vessels. Capillaries form an extensive network, approximately 20 billion in number, of short (hundreds of μm in length), branched, interconnecting vessels that course among the individual cells of the body. This network forms an enormous surface area to make contact with the body’s cells. The flow of blood from a metarteriole through capillaries and into a postcapillary venule (venule that re-
ceives blood from a capillary) is called the microcirculation (micro = small) of the body. The primary function of capillaries is the exchange of substances between the blood and interstitial fluid. Because of this, these thin-walled vessels are referred to as exchange vessels.

Capillaries are found near almost every cell in the body, but their number varies with the metabolic activity of the tissue they serve. Body tissues with high metabolic requirements, such as muscles, the brain, the liver, the kidneys, and the nervous system, use more O₂ and nutrients and thus have extensive capillary networks. Tissues with lower metabolic requirements, such as tendons and ligaments, contain fewer capillaries. Capillaries are absent in a few tissues, such as all covering and lining epithelia, the cornea and lens of the eye, and cartilage.

The structure of capillaries is well suited to their function as exchange vessels because they lack both a tunica media and a tunica externa. Because capillary walls are composed of only a single layer of endothelial cells (see Figure 21.1e) and a basement membrane, a substance in the blood must pass through just one cell layer to reach the interstitial fluid and tissue cells. Exchange of materials occurs only through the walls of capillaries and the beginning of venules; the walls of arteries, arterioles, most venules, and veins present too thick a barrier. Capillaries form extensive branching networks that increase the surface area available for rapid exchange of materials. In most tissues, blood flows through only a small part of the capillary network when metabolic needs are low. However, when a tissue is active, such as contracting muscle, the entire capillary network fills with blood.

Throughout the body, capillaries function as part of a capillary bed (Figure 21.3), a network of 10–100 capillaries that arises from a single metarteriole. In most parts of the body, blood can flow through a capillary network from an arteriole into a venule as follows:

1. **Capillaries.** In this route, blood flows from an arteriole into capillaries and then into venules. As noted earlier, at the junctions between the metarteriole and the capillaries are rings of smooth muscle fibers called precapillary sphincters that control the flow of blood through the capillaries. When the precapillary sphincters are relaxed (open), blood flows into the capillaries (Figure 21.3a); when precapillary sphincters contract (close or partially close), blood flow through the capillaries ceases or decreases (Figure 21.3b). Typically, blood flows intermittently through capillaries due to alternating contraction and relaxation of the smooth muscle of metarterioles and the precapillary sphincters. This intermittent contraction and relaxation, which may occur 5 to 10 times per minute, is called vasomotion. In

**Figure 21.3** Arteriole, capillaries, and venule. Precapillary sphincters regulate the flow of blood through capillary beds.

In capillaries, nutrients, gases, and wastes are exchanged between the blood and interstitial fluid.
part, vasomotion is due to chemicals released by the endothelial cells; nitric oxide is one example. At any given time, blood flows through only about 25% of the capillaries.

2. **Thoroughfare channel.** The proximal end of a metarteriole is surrounded by scattered smooth muscle fibers whose contraction and relaxation help regulate blood flow. The distal end of the vessel has no smooth muscle; it resembles a capillary and is called a thoroughfare channel. Such a channel provides a direct route for blood from an arteriole to a venule, thus bypassing capillaries.

The body contains three different types of capillaries: continuous capillaries, fenestrated capillaries, and sinusoids (Figure 21.4). Most capillaries are **continuous capillaries**, in which the plasma membranes of endothelial cells form a continuous tube that is interrupted only by **intercellular clefts**, gaps between neighboring endothelial cells (Figure 21.4a). Continuous capillaries are found in the brain, lungs, skeletal and smooth muscle, and connective tissues.

Other capillaries of the body are **fenestrated capillaries** (*fenestr-* = window). The plasma membranes of the endothelial cells in these capillaries have many **fenestrations**, small pores (holes) ranging from 70 to 100 nm in diameter (Figure 21.4b). Fenestrated capillaries are found in the kidneys, villi of the small intestine, choroid plexuses of the ventricles in the brain, ciliary processes of the eyes, and endocrine glands.

**Sinusoids** (*sinus* = curve) are wider and more winding than other capillaries. Their endothelial cells may have unusually large fenestrations. In addition to having an incomplete or absent basement membrane (Figure 21.4c), sinusoids have very large intercellular clefts that allow proteins and in some cases even blood cells to pass from a tissue into the bloodstream. For example, newly formed blood cells enter the bloodstream through the sinusoids of red bone marrow. In addition, sinusoids contain specialized lining cells that are adapted to the function of the tissue. Sinusoids in the liver, for example, contain phagocytic cells that remove bacteria and other debris from the blood. The spleen, anterior pituitary, and parathyroid glands also have sinusoids.

Usually blood passes from the heart and then in sequence through arteries, arterioles, capillaries, venules, and veins and then back to the heart. In some parts of the body, however, blood passes from one capillary network into another through a vein called a **portal vein**. Such a circulation of blood is called a **portal system**. The name of the portal system gives the name of the second capillary location. As you will see later, there are portal systems associated with the liver (hepatic portal circulation) and the pituitary gland (hypophyseal portal system).

### Venules

Unlike their thick-walled arterial counterparts, venules (= little vein) and veins have thin walls that do not readily maintain their shape. Venules drain the capillary blood and begin the return flow of blood back toward the heart (see Figure 21.3).

As noted earlier, venules that initially receive blood from capillaries are called **postcapillary venules**. They are the smallest venules, measuring 10 μm to 50 μm in diameter, and have loosely organized intercellular junctions (the weakest endothelial contacts encountered along the entire vascular tree) and thus are very porous. They function as significant sites of exchange of nutrients and wastes and white blood cell emigration, and for this reason form part of the microcirculatory exchange unit along with the capillaries. As the postcapillary venules continue to en-
large, they acquire one or two layers of circularly arranged smooth muscle cells. These muscular venules (50 μm to 200 μm) have thicker walls across which exchanges with the interstitial fluid can no longer occur.

Veins

While veins do show structural changes as they increase in size from small to medium to large, the structural changes are not as distinct as they are in arteries. Veins, in general, have very thin walls relative to their total diameter (average thickness is less than one-tenth of the vessel diameter). They range in size from 0.5 mm in diameter for small veins to 3 cm in the large caval veins entering the heart.

Although veins are composed of essentially the same three layers as arteries, the relative thicknesses of the layers are different. The tunica interna of veins is thinner than that of arteries; the tunica media of veins is much thinner than in arteries, with relatively little smooth muscle and elastic fibers. The tunica externa of veins is the thickest layer and consists of collagen and elastic fibers. Veins lack the internal or external elastic laminae found in arteries (see Figure 22.1b). They are distensible enough to adapt to variations in the volume and pressure of blood passing through them, but are not designed to withstand high pressure. The lumen of a vein is larger than that of a comparable artery, and veins often appear collapsed (flattened) when sectioned.

The pumping action of the heart is a major factor in moving venous blood back to the heart. The contraction of skeletal muscles in the lower limbs also helps boost venous return to the heart (Figure 21.5). The average blood pressure in veins is considerably lower than in arteries. The difference in pressure can be noticed when blood flows from a cut vessel. Blood leaves a cut vein in an even, slow flow but spurts rapidly from a cut artery. Most of the structural differences between arteries and veins reflect this pressure difference. For example, the walls of veins are not as strong as those of arteries.

Many veins, especially those in the limbs, also contain valves, thin folds of tunica interna that form flappelike cusps. The valve cusps project into the lumen, pointing toward the heart (see Figure 21.9). The low blood pressure in veins allows blood returning to the heart to slow and even back up; the valves aid in venous return by preventing the backflow of blood.

A vascular (venous) sinus is a vein with a thin endothelial wall that has no smooth muscle to alter its diameter. In a vascular sinus, the surrounding dense connective tissue replaces the tunica media and tunica externa in providing support. For example, dural venous sinuses, which are supported by the dura mater, convey deoxygenated blood from the brain to the heart. Another example of a vascular sinus is the coronary sinus of the heart (see Figure 20.3c on page 722).

While veins follow paths similar to those of their arterial counterparts, they differ from arteries in a number of ways, aside from the structures of their walls. First, veins are more numerous than arteries for several reasons. Some veins are paired and accompany medium- to small-sized muscular arteries. These double sets of veins escort the arteries and connect with one another via venous channels called anastomotic veins. The anastomotic veins cross the accompanying artery to form ladder-like rungs between the paired veins (see Figure 21.25c). The greatest number of paired veins occurs within the limbs. The subcutaneous layer deep to the skin is another source of veins. These veins, called superficial veins, course through the subcutaneous layer unaccompanied by parallel arteries. Along their course, the superficial veins form small connections (anastomoses) with the deep veins that travel between the skeletal muscles. These connections allow communication between the deep and superficial flow of blood. The amount of blood flow through superficial veins varies from location to location within the body. In the upper limb, the superficial veins are much larger than the deep veins and serve as the major pathways from the capillaries of the upper limb back to the heart. In the lower limb, the opposite is true; the deep veins serve as the principal return pathways. In fact, one-way valves in small anastomosing vessels allow blood to pass from the superficial to the deep veins, but prevent the blood from passing in the reverse direction. This design has important implications in the development of varicose veins.

Figure 21.5 Venous valves.

Valves in veins allow blood to flow in one direction only—toward the heart.

Why are valves more important in arm veins and leg veins than in neck veins?
Leaky venous valves can cause veins to become dilated and twisted in appearance, a condition called varicose veins or varices (VAR-i-se¯z; varic- = a swollen vein). The singular is varix (VAR-iks). The condition may occur in the veins of almost any body part, but it is most common in the esophagus and in superficial veins of the lower limbs. Those in the lower limbs can range from cosmetic problems to serious medical conditions. The valvular defect may be congenital or may result from mechanical stress (prolonged standing or pregnancy) or aging. The leaking venous valves allow the backflow of blood from the deep veins to the less efficient superficial veins, where the blood pools. This creates pressure that distends the vein and allows fluid to leak into surrounding tissue. As a result, the affected vein and the tissue around it may become inflamed and painfully tender. Veins close to the surface of the legs, especially the saphenous vein, are highly susceptible to varicosities; deeper veins are not as vulnerable because surrounding skeletal muscles prevent their walls from stretching excessively. Varicose veins in the anal canal are referred to as hemorrhoids. Esophageal varices result from dilated veins in the walls of the lower part of the esophagus.

esophagus and sometimes the upper part of the stomach. Bleeding esophageal varices are life-threatening and are usually a result of chronic liver disease.

Several treatment options are available for varicose veins in the lower limbs. Elastic stockings (support hose) may be used for individuals with mild symptoms or for whom other options are not recommended. Sclerotherapy involves injection of a solution into varicose veins that damages the tunica interna by producing a harmless superficial thrombophlebitis (inflammation involving a blood clot). Healing of the damaged part leads to scar formation that occludes the vein. Radiofrequency endovenous occlusion involves the application of radiofrequency energy to heat up and close off varicose veins. Laser occlusion uses laser therapy to shut down veins. In a surgical procedure called stripping, veins may be removed. In this procedure, a flexible wire is threaded through the vein and then pulled out to strip (remove) it from the body.

A summary of the distinguishing features of blood vessels is presented in Table 21.1 on page 768.

**Blood Distribution**

The largest portion of your blood volume at rest—about 64%—is in systemic veins and venules (Figure 21.6). Systemic arteries and arterioles hold about 13% of the blood volume, systemic capillaries hold about 7%, pulmonary blood vessels hold about 9%, and the heart holds about 7%. Because systemic veins and venules contain a large percentage of the blood volume, they function as **blood reservoirs** from which blood can be diverted quickly if the need arises. For example, during increased muscular activity, the cardiovascular center in the brain stem sends a larger number of sympathetic impulses to veins. The result is venoconstriction, constriction of veins, which reduces the volume of blood in reservoirs and allows a greater blood volume to flow to skeletal muscles, where it is needed most. A similar mechanism operates in cases of hemorrhage, when blood volume and pressure decrease; in this case, venoconstriction helps counteract the drop in blood pressure. Among the principal blood reservoirs are the veins of the abdominal organs (especially the liver and spleen) and the veins of the skin.

**CHECKPOINT**

1. What is the function of elastic fibers and smooth muscle in the tunica media of arteries?
2. How are elastic arteries and muscular arteries different?
3. What structural features of capillaries allow the exchange of materials between blood and body cells?
4. What is the difference between pressure reservoirs and blood reservoirs? Why is each important?
5. What is the relationship between anastomoses and collateral circulation?

**CAPILLARY EXCHANGE**

**OBJECTIVE**

- Discuss the pressures that cause movement of fluids between capillaries and interstitial spaces.

The mission of the entire cardiovascular system is to keep blood flowing through capillaries to allow **capillary exchange**, the movement of substances between blood and interstitial fluid. The 7% of the blood in systemic capillaries at any given time is continually exchanging materials with interstitial fluid. Substances enter and leave capillaries by three basic mechanisms: diffusion, transcytosis, and bulk flow.

**Diffusion**

The most important method of capillary exchange is simple diffusion. Many substances, such as oxygen (O₂), carbon dioxide (CO₂), glucose, amino acids, and hormones, enter and leave capillaries by simple diffusion. Because O₂ and nutrients normally are present in higher concentrations in blood, they diffuse down their concentration gradients into interstitial fluid and then into body cells. CO₂ and other wastes released by body cells are present in higher concentrations in interstitial fluid, so they diffuse into blood.

Substances in blood or interstitial fluid can cross the walls of a capillary by diffusing through the intercellular clefts or fenestrations or by diffusing through the endothelial cells (see Figure 21.4). Water-soluble substances such as glucose and amino acids pass across capillary walls through intercellular clefts or fenestrations. Lipid-soluble materials, such as O₂, CO₂, and steroid hormones, may pass across capillary walls directly through the lipid bilayer of endothelial cell plasma membranes.
Most plasma proteins and red blood cells cannot pass through capillary walls of continuous and fenestrated capillaries because they are too large to fit through the intercellular clefts and fenestrations.

In sinusoids, however, the intercellular clefts are so large that they allow even proteins and blood cells to pass through their walls. For example, hepatocytes (liver cells) synthesize and release many plasma proteins, such as fibrinogen (the main clotting protein) and albumin, which then diffuse into the bloodstream through sinusoids. In red bone marrow, blood cells are formed (hemopoiesis) and then enter the bloodstream through sinusoids.

In contrast to sinusoids, the capillaries of the brain allow only a few substances to move across their walls. Most areas of the brain contain continuous capillaries; however, these capillaries are very “tight.” The endothelial cells of most brain capillaries are sealed together by tight junctions. The resulting blockade to movement of materials into and out of brain capillaries is known as the blood–brain barrier (see page 498). In brain areas that lack the blood–brain barrier, for example, the hypothalamus, pineal gland, and pituitary gland, materials undergo capillary exchange more freely.

**Transcytosis**

A small quantity of material crosses capillary walls by transcytosis (trans- = across; cyt- = cell; -osis = process). In this process, substances in blood plasma become enclosed within tiny pinocytic vesicles that first enter endothelial cells by exocytosis, then move across the cell and exit on the other side by exocytosis. This method of transport is important mainly for large, lipid-insoluble molecules that cannot cross capillary walls in any other way. For example, the hormone insulin (a small protein) enters the bloodstream by transcytosis, and certain antibodies (also proteins) pass from the maternal circulation into the fetal circulation by transcytosis.

**Bulk Flow: Filtration and Reabsorption**

**Bulk flow** is a passive process in which large numbers of ions, molecules, or particles in a fluid move together in the same direction. The substances move at rates far greater than can be accounted for by diffusion alone. Bulk flow occurs from an area of higher pressure to an area of lower pressure, and it continues as long as a pressure difference exists. Diffusion is more important for solute exchange between blood and interstitial fluid, but bulk flow is more important for regulation of the relative volumes of blood and interstitial fluid. Pressure-driven movement of fluid and solutes from blood capillaries into interstitial fluid is called filtration. Pressure-driven movement from interstitial fluid into blood capillaries is called reabsorption.

Two pressures promote filtration: blood hydrostatic pressure (BHP), the pressure generated by the pumping action of the heart, and interstitial fluid osmotic pressure. The main pressure promoting reabsorption of fluid is blood colloid osmotic pressure. The balance of these pressures, called net filtration pressure (NFP), determines whether the volumes of blood and interstitial fluid remain steady or change. Overall, the volume of fluid and solutes reabsorbed normally is almost as large as the volume filtered. This near equilibrium is known as Starling’s law of the capillaries. Let’s see how these hydrostatic and osmotic pressures balance.

Within vessels, the hydrostatic pressure is due to the pressure that water in blood plasma exerts against blood vessel walls. The blood hydrostatic pressure (BHP) is about 35 millimeters of mercury (mmHg) at the arterial end of a capillary, and about 16 mmHg at the capillary’s venous end (Figure 21.7). BHP “pushes” fluid out of capillaries into interstitial fluid. The opposing pressure of the interstitial fluid, called interstitial fluid hydrostatic pressure (IFHP), “pushes” fluid from interstitial spaces back into capillaries. However, IFHP is close to zero. (IFHP is difficult to measure, and its reported values vary from small positive values to small negative values.) For our discussion we assume that IFHP equals 0 mmHg all along the capillaries.

The difference in osmotic pressure across a capillary wall is due almost entirely to the presence in blood of plasma proteins, which are too large to pass through either fenestrations or gaps between endothelial cells. Blood colloid osmotic pressure (BCOP) is a force caused by the colloidal suspension of these large proteins in plasma that averages 26 mmHg in most capillaries. The effect of BCOP is to “pull” fluid from interstitial spaces into capillaries. Opposing BCOP is interstitial fluid osmotic pressure (IFOP), which “pulls” fluid out of capillaries into interstitial fluid. Normally, IFOP is very small—0.1–5 mmHg—because only tiny amounts of protein are present in interstitial fluid. The small amount of protein that leaks from blood plasma into interstitial fluid does not accumulate there because it passes into lymph in lymphatic capillaries and is eventually returned to the blood. For discussion, we can use a value of 1 mmHg for IFOP.

Whether fluids leave or enter capillaries depends on the balance of pressures. If the pressures that push fluid out of capillaries exceed the pressures that pull fluid into capillaries, fluid will move from capillaries into interstitial spaces (filtration). If, however, the pressures that push fluid out of interstitial spaces into capillaries exceed the pressures that pull fluid out of capillaries, then fluid will move from interstitial spaces into capillaries (reabsorption).

The net filtration pressure (NFP), which indicates the direction of fluid movement, is calculated as follows:

\[
NFP = (BHP + IFOP) - (BCOP + IFHP)
\]

At the arterial end of a capillary,

\[
NFP = (35 + 1) \text{ mmHg} - (26 + 0) \text{ mmHg} = 36 - 26 \text{ mmHg} = 10 \text{ mmHg}
\]
Thus, at the arterial end of a capillary, there is a net outward pressure of 10 mmHg, and fluid moves out of the capillary into interstitial spaces (filtration).

At the venous end of a capillary,

\[ \text{NFP} = (16 + 1) \text{ mmHg} - (26 + 0) \text{ mmHg} = 17 - 26 \text{ mmHg} = -9 \text{ mmHg} \]

At the venous end of a capillary, the negative value (−9 mmHg) represents a net inward pressure, and fluid moves into the capillary from tissue spaces (reabsorption).

On average, about 85% of the fluid filtered out of capillaries is reabsorbed. The excess filtered fluid and the few plasma proteins that do escape from blood into interstitial fluid enter lymphatic capillaries (see Figure 22.2 on page 834). As lymph drains into the junction of the jugular and subclavian veins in the upper thorax (see Figure 22.3 on page 835), these materials return to the blood. Every day about 20 liters of fluid filter out of capillaries in tissues throughout the body. Of this fluid, 17 liters are reabsorbed and 3 liters enter lymphatic capillaries (excluding filtration during urine formation).

**Figure 21.7** Dynamics of capillary exchange (Starling’s law of the capillaries). Excess filtered fluid drains into lymphatic capillaries.

Blood hydrostatic pressure pushes fluid out of capillaries (filtration), and blood colloid osmotic pressure pulls fluid into capillaries (reabsorption).

A person who has liver failure cannot synthesize the normal amount of plasma proteins. How does a deficit of plasma proteins affect blood colloid osmotic pressure, and what is the effect on capillary filtration and reabsorption?
6. How can substances enter and leave blood plasma?
7. How do hydrostatic and osmotic pressures determine fluid movement across the walls of capillaries?
8. Define edema and describe how it develops.

HEMODYNAMICS: FACTORS AFFECTING BLOOD FLOW

• CLINICAL CONNECTION Edema

If filtration greatly exceeds reabsorption, the result is edema (= swelling), an abnormal increase in interstitial fluid volume. Edema is not usually detectable in tissues until interstitial fluid volume has risen to 30% above normal. Edema can result from either excess filtration or inadequate reabsorption.

Two situations may cause excess filtration:

• Increased capillary blood pressure causes more fluid to be filtered from capillaries.
• Increased permeability of capillaries raises interstitial fluid osmotic pressure by allowing some plasma proteins to escape. Such leakiness may be caused by the destructive effects of chemical, bacterial, thermal, or mechanical agents on capillary walls.

One situation commonly causes inadequate reabsorption:

• Decreased concentration of plasma proteins lowers the blood colloid osmotic pressure. Inadequate synthesis or dietary intake or loss of plasma proteins is associated with liver disease, burns, malnutrition (for example, kwashiorkor, see page 1013), and kidney disease.

Blood Pressure

As you have just learned, blood flows from regions of higher pressure to regions of lower pressure; the greater the pressure difference, the greater the blood flow. Contraction of the ventricles generates blood pressure (BP), the hydrostatic pressure exerted by blood on the walls of a blood vessel. BP is determined by cardiac output (see page 741), blood volume, and vascular resistance (described shortly). BP is highest in the aorta and large systemic arteries; in a resting, young adult, BP rises to about 110 mmHg during systole (ventricular contraction) and drops to about 70 mmHg during diastole (ventricular relaxation).

Systolic blood pressure is the highest pressure attained in arteries during systole, and diastolic blood pressure is the lowest arterial pressure during diastole (Figure 21.8). As blood leaves the aorta and flows through the systemic circulation, its pressure falls progressively as the distance from the left ventricle increases. Blood pressure decreases to about 35 mmHg as blood passes from systemic arteries through systemic arterioles and into capillaries, where the pressure fluctuations disappear. At the venous end of capillaries, blood pressure has dropped to about the greater the blood flow. But the higher the resistance, the smaller the blood flow.

Figure 21.8 Blood pressures in various parts of the cardiovascular system. The dashed line is the mean (average) blood pressure in the aorta, arteries, and arterioles.

Blood pressure rises and falls with each heartbeat in blood vessels leading to capillaries.
16 mmHg. Blood pressure continues to drop as blood enters systemic venules and then veins because these vessels are farthest from the left ventricle. Finally, blood pressure reaches 0 mmHg as blood flows into the right ventricle.

**Mean arterial pressure (MAP),** the average blood pressure in arteries, is roughly one-third of the way between the diastolic and systolic pressures. It can be estimated as follows:

\[
\text{MAP} = \text{diastolic BP} + \frac{1}{3} (\text{systolic BP} - \text{diastolic BP})
\]

Thus, in a person whose BP is 110/70 mmHg, MAP is about 83 mmHg \((70 + \frac{1}{3}(110 - 70))\).

We have already seen that cardiac output equals heart rate multiplied by stroke volume. Another way to calculate cardiac output is to divide mean arterial pressure (MAP) by resistance (R): \(\text{CO} = \text{MAP} \div \text{R}\). By rearranging the terms of this equation, you can see that \(\text{MAP} = \text{CO} \times \text{R}\). If cardiac output rises due to an increase in stroke volume or heart rate, then the mean arterial pressure rises as long as resistance remains steady. Likewise, a decrease in cardiac output causes a decrease in mean arterial pressure if resistance does not change.

Blood pressure also depends on the total volume of blood in the cardiovascular system. The normal volume of blood in an adult is about 5 liters (5.3 qt). Any decrease in this volume, as from hemorrhage, decreases the amount of blood that is circulated through the arteries each minute. A modest decrease can be compensated for by homeostatic mechanisms that help maintain blood pressure (described on page 755), but if the decrease in blood volume is greater than 10% of the total, blood pressure drops. Conversely, anything that increases blood volume, such as water retention in the body, tends to increase blood pressure.

**Vascular Resistance**

As noted earlier, **vascular resistance** is the opposition to blood flow due to friction between blood and the walls of blood vessels. Vascular resistance depends on (1) size of the blood vessel lumen, (2) blood viscosity, and (3) total blood vessel length.

1. **Size of the lumen.** The smaller the lumen of a blood vessel, the greater its resistance to blood flow. Resistance is inversely proportional to the fourth power of the diameter \((d)\) of the blood vessel’s lumen \((R \propto \frac{1}{d^4})\). The smaller the diameter of the blood vessel, the greater the resistance it offers to blood flow. For example, if the diameter of a blood vessel decreases by one-half, its resistance to blood flow increases 16 times. Vasoconstriction narrows the lumen, and vasodilation widens it. Normally, moment-to-moment fluctuations in blood flow through a given tissue are due to vasoconstriction and vasodilation of the tissue’s arterioles. As arterioles dilate, resistance decreases, and blood pressure falls. As arterioles constrict, resistance increases, and blood pressure rises.

2. **Blood viscosity.** The viscosity (thickness) of blood depends mostly on the ratio of red blood cells to plasma (fluid) volume, and to a smaller extent on the concentration of proteins in plasma. The higher the blood’s viscosity, the higher the resistance. Any condition that increases the viscosity of blood, such as dehydration or polycythemia (an unusually high number of red blood cells), thus increases blood pressure. A depletion of plasma proteins or red blood cells, due to anemia or hemorrhage, decreases viscosity and thus decreases blood pressure.

3. **Total blood vessel length.** Resistance to blood flow through a vessel is directly proportional to the length of the blood vessel. The longer a blood vessel, the greater the resistance. Obese people often have hypertension (elevated blood pressure) because the additional blood vessels in their adipose tissue increase their total blood vessel length. An estimated 650 km (about 400 miles) of additional blood vessels develop for each extra kilogram (2.2 lb) of fat.

**Systemic vascular resistance (SVR),** also known as total peripheral resistance (TPR), refers to all the vascular resistances offered by systemic blood vessels. The diameters of arteries and veins are large, so their resistance is very small because most of the blood does not come into physical contact with the walls of the blood vessel. The smallest vessels—arterioles, capillaries, and venules—contribute the most resistance. A major function of arterioles is to control SVR—and therefore blood pressure and blood flow to particular tissues—by changing their diameters. Arterioles need to vasodilate or vasoconstrict only slightly to have a large effect on SVR. The main center for regulation of SVR is the vasomotor center in the brain stem (described shortly).

**Venous Return**

**Venous return,** the volume of blood flowing back to the heart through the systemic veins, occurs due to the pressure generated by contractions of the heart’s left ventricle. The pressure difference from venules (averaging about 16 mmHg) to the right ventricle (0 mmHg), although small, normally is sufficient to cause venous return to the heart. If pressure increases in the right atrium or ventricle, venous return will decrease. One cause of increased pressure in the right atrium is an incompetent (leaky) tricuspid valve, which lets blood regurgitate (flow backward) as the ventricles contract. The result is decreased venous return and buildup of blood on the venous side of the systemic circulation.

When you stand up, for example, at the end of an anatomy and physiology lecture, the pressure pushing blood up the veins in your lower limbs is barely enough to overcome the force of gravity pushing it back down. Besides the heart, two other mechanisms “pump” blood from the lower body back to the heart: (1) the skeletal muscle pump, and (2) the respiratory pump. Both pumps depend on the presence of valves in veins.

The **skeletal muscle pump** operates as follows (Figure 21.9):

1. While you are standing at rest, both the venous valve closer to the heart (proximal valve) and the one farther from the heart (distal valve) in this part of the leg are open, and blood flows upward toward the heart.
Contraction of leg muscles, such as when you stand on tip-toes or take a step, compresses the vein. The compression pushes blood through the proximal valve, an action called milking. At the same time, the distal valve in the uncompressed segment of the vein closes as some blood is pushed against it. People who are immobilized through injury or disease lack these contractions of leg muscles. As a result, their venous return is slower and they may develop circulation problems.

Just after muscle relaxation, pressure falls in the previously compressed section of vein, which causes the proximal valve to close. The distal valve now opens because blood pressure in the foot is higher than in the leg, and the vein fills with blood from the foot.

The respiratory pump is also based on alternating compression and decompression of veins. During inhalation, the diaphragm moves downward, which causes a decrease in pressure in the thoracic cavity and an increase in pressure in the abdominal cavity. As a result, abdominal veins are compressed, and a greater volume of blood moves from the compressed abdominal veins into the decompressed thoracic veins and then into the right atrium. When the pressures reverse during exhalation, the valves in the veins prevent backflow of blood from the thoracic veins to the abdominal veins.

Figure 21.10 summarizes the factors that increase blood pressure through increasing cardiac output or systemic vascular resistance.

**Velocity of Blood Flow**

Earlier we saw that blood flow is the volume of blood that flows through any tissue in a given time period (in mL/min). The speed or velocity of blood flow (in cm/sec) is inversely related to the cross-sectional area. Velocity is slowest where the total cross-sectional area is greatest (Figure 21.11). Each time an artery branches, the total cross-sectional area of all its branches is greater than the cross-sectional area of the original vessel, so blood flow becomes slower and slower as blood moves further away from the heart, and is slowest in the capillaries. Conversely, when venules unite to form veins, the total cross-sectional area becomes smaller and flow becomes faster. In an adult, the cross-sectional area of the aorta is only 3–5 cm², and the average velocity of the blood there is 40 cm/sec. In capillaries, the total cross-sectional area is 4500–6000 cm², and the velocity of blood flow is less than 0.1 cm/sec. In the two venae cavae combined, the cross-sectional area is about 14 cm², and the velocity is about 15 cm/sec. Thus, the velocity of blood flow decreases as blood flows from the aorta to arteries to arterioles to capillaries, and increases as it leaves capillaries and returns to the heart. The relatively slow rate of flow through capillaries aids the exchange of materials between blood and interstitial fluid.

**Circulation time** is the time required for a drop of blood to pass from the right atrium, through the pulmonary circulation, back to the left atrium, through the systemic circulation down to the foot, and back again to the right atrium. In a resting person, circulation time normally is about 1 minute.

**CLINICAL CONNECTION**

**Syncope**

Syncope (SIN-kō-pe), or fainting, is a sudden, temporary loss of consciousness that is not due to head trauma, followed by spontaneous recovery. It is most commonly due to cerebral ischemia, lack of sufficient blood flow to the brain. Syncope may occur for several reasons:

- *Vasodepressor syncope* is due to sudden emotional stress or real, threatened, or fantasized injury.
- *Situational syncope* is caused by pressure stress associated with urination, defecation, or severe coughing.
- *Drug-induced syncope* may be caused by drugs such as antihypertensives, diuretics, vasodilators, and tranquilizers.
- *Orthostatic hypotension*, an excessive decrease in blood pressure that occurs upon standing up, may cause fainting.

**Aside from cardiac contractions, what mechanisms act as pumps to boost venous return?**
Figure 21.10  Summary of factors that increase blood pressure. Changes noted within green boxes increase cardiac output; changes noted within blue boxes increase systemic vascular resistance.

Increases in cardiac output and increases in systemic vascular resistance will increase mean arterial pressure.

Figure 21.11  Relationship between velocity (speed) of blood flow and total cross-sectional area in different types of blood vessels.

Velocity of blood flow is slowest in the capillaries because they have the largest total cross-sectional area.

¿ In which blood vessels is the velocity of flow fastest?

¿ Which type of blood vessel exerts the major control of systemic vascular resistance, and how does it achieve this?

CHECKPOINT

9. Explain how blood pressure and resistance determine volume of blood flow.
10. What is systemic vascular resistance and what factors contribute to it?
11. How is the return of venous blood to the heart accomplished?
12. Why is the velocity of blood flow faster in arteries and veins than in capillaries?

CONTROL OF BLOOD PRESSURE AND BLOOD FLOW

OBJECTIVE

• Describe how blood pressure is regulated.

Several interconnected negative feedback systems control blood pressure by adjusting heart rate, stroke volume, systemic vascular resistance, and blood volume. Some systems allow rapid adjustments to cope with sudden changes, such as the drop in blood pressure in the brain that occurs when you get out of bed; others act more slowly to provide long-term regulation of blood pressure. The body may also require adjustments to the distribution of blood flow. During exercise, for example, a greater percentage of the total blood flow is diverted to skeletal muscles.
Role of the Cardiovascular Center

In Chapter 20, we noted how the cardiovascular (CV) center in the medulla oblongata helps regulate heart rate and stroke volume. The CV center also controls neural, hormonal, and local negative feedback systems that regulate blood pressure and blood flow to specific tissues. Groups of neurons scattered within the CV center regulate heart rate, contractility (force of contraction) of the ventricles, and blood vessel diameter. Some neurons stimulate the heart (cardiostimulatory center); others inhibit the heart (cardioinhibitory center). Still others control blood vessel diameter by causing constriction (vasoconstrictor center) or dilation (vasodilator center); these neurons are referred to collectively as the vasomotor center. Because the CV center neurons communicate with one another, function together, and are not clearly separated anatomically, we discuss them here as a group.

The cardiovascular center receives input both from higher brain regions and from sensory receptors (Figure 21.12). Nerve impulses descend from the cerebral cortex, limbic system, and hypothalamus to affect the cardiovascular center. For example, even before you start to run a race, your heart rate may increase due to nerve impulses conveyed from the limbic system to the CV center. If your body temperature rises during a race, the hypothalamus sends nerve impulses to the CV center. The resulting vasodilation of skin blood vessels allows heat to dissipate more rapidly from the surface of the skin. The three main types of sensory receptors that provide input to the cardiovascular center are proprioceptors, baroreceptors, and chemoreceptors. Proprioceptors monitor movements of joints and muscles and provide input to the cardiovascular center during physical activity. Their activity accounts for the rapid increase in heart rate at the beginning of exercise. Baroreceptors monitor changes in pressure and stretch in the walls of blood vessels, and chemoreceptors monitor the concentration of various chemicals in the blood.

Output from the cardiovascular center flows along sympathetic and parasympathetic neurons of the ANS (Figure 21.12). Sympathetic impulses reach the heart via the cardiac accelerator nerves. An increase in sympathetic stimulation increases heart rate and contractility; a decrease in sympathetic stimulation decreases heart rate and contractility. Parasympathetic stimulation, conveyed along the vagus (X) nerves, decreases heart rate. Thus, opposing sympathetic (stimulatory) and parasympathetic (inhibitory) influences control the heart.

The cardiovascular center also continually sends impulses to smooth muscle in blood vessel walls via vasomotor nerves. These sympathetic neurons exit the spinal cord through all thoracic and the first one or two lumbar spinal nerves and then pass into the sympathetic trunk ganglia (see Figure 15.2 on page 550). From there, impulses propagate along sympathetic neurons that innervate blood vessels in viscera and peripheral areas. The vasomotor region of the cardiovascular center continually sends impulses over these routes to arterioles throughout the body, but especially to those in the skin and abdominal viscera. The result is a moderate state of tonic contraction or vasoconstriction, called vasomotor tone, that sets the resting level of systemic vascular resistance. Sympathetic stimu-
Neural Regulation of Blood Pressure

The nervous system regulates blood pressure via negative feedback loops that occur as two types of reflexes: baroreceptor reflexes and chemoreceptor reflexes.

**Baroreceptor Reflexes**

Baroreceptors, pressure-sensitive sensory receptors, are located in the aorta, internal carotid arteries (arteries in the neck that supply blood to the brain), and other large arteries in the neck and chest. They send impulses to the cardiovascular center to help regulate blood pressure. The two most important baroreceptor reflexes are the carotid sinus reflex and the aortic reflex.

Baroreceptors in the wall of the carotid sinuses initiate the carotid sinus reflex, which helps regulate blood pressure in the brain. The carotid sinuses are small widenings of the right and left internal carotid arteries just above the point where they branch from the common carotid arteries (Figure 21.13). Blood pressure stretches the wall of the carotid sinus, which stimulates the baroreceptors. Nerve impulses propagate from the carotid sinus baroreceptors over sensory axons in the glossopharyngeal (IX) nerves to the cardiovascular center in the medulla oblongata. Baroreceptors in the wall of the ascending aorta and arch of the aorta initiate the aortic reflex, which regulates systemic blood pressure. Nerve impulses from aortic baroreceptors reach the cardiovascular center via sensory axons of the vagus (X) nerves.

When blood pressure falls, the baroreceptors are stretched less, and they send nerve impulses at a slower rate to the cardiovascular center (Figure 21.14). In response, the CV center decreases parasympathetic stimulation of the heart by way of motor axons of the vagus nerves and increases sympathetic stimulation of the heart via cardiac accelerator nerves. Another consequence of increased sympathetic stimulation is increased secretion of epinephrine and norepinephrine by the adrenal medulla. As the heart beats faster and more forcefully, and as systemic vascular resistance increases, cardiac output and systemic vascular resistance rise, and blood pressure increases to the normal level.

Conversely, when an increase in pressure is detected, the baroreceptors send impulses at a faster rate. The CV center responds by increasing parasympathetic stimulation and decreasing sympathetic stimulation. The resulting decreases in heart rate and force of contraction reduce the cardiac output. The cardiovascular center also slows the rate at which it sends sympathetic impulses along vasomotor neurons that normally cause vasoconstriction. The resulting vasodilation lowers systemic vascular resistance. Decreased cardiac output and decreased systemic vascular resistance both lower systemic arterial blood pressure to the normal level.

**Figure 21.13** ANS innervation of the heart and the baroreceptor reflexes that help regulate blood pressure.

Baroreceptors are pressure-sensitive neurons that monitor stretching.

**Key:**
- Sensory (afferent) neurons
- Motor (efferent) neurons

**Question:** Which cranial nerves conduct impulses to the cardiovascular center from baroreceptors in the carotid sinuses and the arch of the aorta?
Moving from a prone (lying down) to an erect position decreases blood pressure and blood flow in the head and upper part of the body. The baroreceptor reflexes, however, quickly counteract the drop in pressure. Sometimes these reflexes operate more slowly than normal, especially in the elderly, in which case a person can faint due to reduced brain blood flow upon standing up too quickly.

**Figure 21.14** Negative feedback regulation of blood pressure via baroreceptor reflexes.

When blood pressure decreases, heart rate increases.

- Some stimulus disrupts homeostasis by decreasing blood pressure.
- Control centers (CV center in medulla oblongata and adrenal medulla) send input to baroreceptors in arch of aorta and carotid sinus, which are stretched less.
- Input: Decreased rate of nerve impulses.
- Output: Increased sympathetic, decreased parasympathetic stimulation, increased secretion of epinephrine and norepinephrine from adrenal medulla.
- Effectors: Increased stroke volume and heart rate lead to increased cardiac output (CO), constriction of blood vessels increases systemic vascular resistance (SVR), increased blood pressure.

Does this negative feedback cycle represent the changes that occur when you lie down or when you stand up?

**Chemoreceptor Reflexes**

Chemoreceptors, sensory receptors that monitor the chemical composition of blood, are located close to the baroreceptors of the carotid sinus and arch of the aorta in small structures called carotid bodies and aortic bodies, respectively. These chemoreceptors detect changes in blood level of O₂, CO₂, and H⁺. Hypoxia (lowered O₂ availability), acidosis (an increase in H⁺ concentration), or hypercapnia (excess CO₂) stimulates the chemoreceptors to send impulses to the cardiovascular center. In response, the CV center increases sympathetic stimulation to arterioles and veins, producing vasoconstriction and an increase in blood pressure. These chemoreceptors also provide input to the respiratory center in the brain stem to adjust the rate of breathing.

**Hormonal Regulation of Blood Pressure**

As you learned in Chapter 18, several hormones help regulate blood pressure and blood flow by altering cardiac output, changing systemic vascular resistance, or adjusting the total blood volume:

1. **Renin–angiotensin–aldosterone (RAA) system.** When blood volume falls or blood flow to the kidneys decreases, juxtaglomerular cells in the kidneys secrete renin into the bloodstream. In sequence, renin and angiotensin converting enzyme (ACE) act on their substrates to produce the active hormone angiotensin II, which raises blood pressure in two ways. First, angiotensin II is a potent vasoconstrictor; it raises blood pressure by increasing systemic vascular resistance. Second, it stimulates secretion of aldosterone, which increases reabsorption of sodium ions (Na⁺) and water by the kidneys. The water reabsorption increases total blood volume, which increases blood pressure. (See page 783.)
2. **Epinephrine and norepinephrine.** In response to sympathetic stimulation, the adrenal medulla releases epinephrine and norepinephrine. These hormones increase cardiac output by increasing the rate and force of heart contractions. They also cause vasoconstriction of arterioles and veins in the skin and abdominal organs and vasodilation of arterioles in cardiac and skeletal muscle, which helps increase blood flow to muscle during exercise. (See Figure 18.20 on page 677.)

3. **Antidiuretic hormone (ADH).** ADH is produced by the hypothalamus and released from the posterior pituitary in response to dehydration or decreased blood volume. Among other actions, ADH causes vasoconstriction, which increases blood pressure. For this reason ADH is also called vasopressin. (See Figure 18.9 on page 657.)

4. **Atrial natriuretic peptide (ANP).** Released by cells in the atria of the heart, ANP lowers blood pressure by causing vasodilation and by promoting the loss of salt and water in the urine, which reduces blood volume.

Table 21.2 summarizes the regulation of blood pressure by hormones.

### Autoregulation of Blood Pressure

In each capillary bed, local changes can regulate vasomotion. When vasodilators produce local dilation of arterioles and relaxation of precapillary sphincters, blood flow into capillary networks is increased, which increases O$_2$ level. Vasconstrictors have the opposite effect. The ability of a tissue to automatically adjust its blood flow to match its metabolic demands is called autoregulation. In tissues such as the heart and skeletal muscle, where the demand for O$_2$ and nutrients and for the removal of wastes can increase as much as tenfold during physical activity, autoregulation is an important contributor to increased blood flow through the tissue. Autoregulation also controls regional blood flow in the brain; blood distribution to various parts of the brain changes dramatically for different mental and physical activities. During a conversation, for example, blood flow increases to your motor speech areas when you are talking and increases to the auditory areas when you are listening.

Two general types of stimuli cause autoregulatory changes in blood flow:

1. **Physical changes.** Warming promotes vasodilation, and cooling causes vasoconstriction. In addition, smooth muscle in arteriole walls exhibits a myogenic response—it contracts more forcefully when it is stretched and relaxes when stretching lessens. If, for example, blood flow through an arteriole decreases, stretching of the arteriole walls decreases. As a result, the smooth muscle relaxes and produces vasodilation, which increases blood flow.

2. **Vasodilating and vasoconstricting chemicals.** Several types of cells—including white blood cells, platelets, smooth muscle fibers, macrophages, and endothelial cells—release a wide variety of chemicals that alter blood-vessel diameter. Vasodilating chemicals released by metabolically active tissue cells include K$^+$, H$^+$, lactic acid (lactate), and adenosine (from ATP). Another important vasodilator released by endothelial cells is nitric oxide (NO). Tissue trauma or inflammation causes release of vasodilating kinins and histamine. Vasconstrictors include thromboxane A2, superoxide radicals, serotonin (from platelets), and endothelins (from endothelial cells).

An important difference between the pulmonary and systemic circulations is their autoregulatory response to changes in O$_2$ level. The walls of blood vessels in the systemic circulation dilate in response to low O$_2$. With vasodilation, O$_2$ delivery increases, which restores the normal O$_2$ level. By contrast, the walls of blood vessels in the pulmonary circulation constrict in response to low levels of O$_2$. This response ensures that blood mostly bypasses those alveoli (air sacs) in the lungs that are poorly ventilated by fresh air. Thus, most blood flows to better-ventilated areas of the lung.

*Acts at α$_1$ receptors in arterioles of abdomen and skin.

1 Acts at β$_2$ receptors in arterioles of cardiac and skeletal muscle; norepinephrine has a much smaller vasodilating effect.

### CHECKPOINT

13. What are the principal inputs to and outputs from the cardiovascular center?

14. Explain the operation of the carotid sinus reflex and the aortic reflex.

15. What is the role of chemoreceptors in the regulation of blood pressure?

16. How do hormones regulate blood pressure?

17. What is autoregulation, and how does it differ in the systemic and pulmonary circulations?
OBJECTIVE
- Define pulse, and define systolic, diastolic, and pulse pressures.

Pulse
The alternate expansion and recoil of elastic arteries after each systole of the left ventricle creates a traveling pressure wave that is called the pulse. The pulse is strongest in the arteries closest to the heart, becomes weaker in the arterioles, and disappears altogether in the capillaries. The pulse may be felt in any artery that lies near the surface of the body that can be compressed against a bone or other firm structure. Table 21.3 depicts some common pulse points.

The pulse rate normally is the same as the heart rate, about 70 to 80 beats per minute at rest. Tachycardia (tak′-i-KAR-dē-a; tachy- = fast) is a rapid resting heart or pulse rate over 100 beats/min. Bradycardia (brād′-i-KAR-dē-a; brady- = slow) is a slow resting heart or pulse rate under 50 beats/min. Endurance-trained athletes normally exhibit bradycardia.

Measuring Blood Pressure
In clinical use, the term blood pressure usually refers to the pressure in arteries generated by the left ventricle during systole and the pressure remaining in the arteries when the ventricle is in diastole. Blood pressure is usually measured in the brachial artery in the left arm (Table 21.3). The device used to measure blood pressure is a sphygmomanometer (sfig′-mō-ma-NOM-e-ter; sphygmo- = pulse; manometer = instrument used to measure pressure). It consists of a rubber cuff connected to a rubber bulb that is used to inflate the cuff and a meter that registers the pressure in the cuff. With the arm resting on a table so that it is about the same level as the heart, the cuff of the sphygmo-

manometer is wrapped around a bared arm. The cuff is inflated by squeezing the bulb until the brachial artery is compressed and blood flow stops, about 30 mmHg higher than the person’s usual systolic pressure. The technician places a stethoscope below the cuff on the brachial artery, and slowly deflates the cuff. When the cuff is deflated enough to allow the artery to open, a spurt of blood passes through, resulting in the first sound heard through the stethoscope. This sound corresponds to systolic blood pressure (SBP), the force of blood pressure on arterial walls just after ventricular contraction (Figure 21.15). As the cuff is deflated further, the sounds suddenly become too faint to be heard through the stethoscope. This level, called the diastolic blood pressure (DBP), represents the force exerted by the blood remaining in arteries during ventricular relaxation. At pressures below diastolic blood pressure, sounds disappear altogether. The various sounds that are heard while taking blood pressure are called Korotkoff sounds (kō-ROT-kof).

The normal blood pressure of an adult male is less than 120 mmHg systolic and less than 80 mmHg diastolic. For example, “110 over 70” (written as 110/70) is a normal blood pressure. In young adult females, the pressures are 8 to 10 mmHg less. People who exercise regularly and are in good physical condition may have even lower blood pressures. Thus, blood pressure slightly lower than 120/80 may be a sign of good health and fitness.

The difference between systolic and diastolic pressure is called pulse pressure. This pressure, normally about 40 mmHg, provides information about the condition of the cardiovascular system. For example, conditions such as atherosclerosis and patent (open) ductus arteriosus greatly increase pulse pressure. The normal ratio of systolic pressure to diastolic pressure to pulse pressure is about 3:2:1.

**Figure 21.15** Relationship of blood pressure changes to cuff pressure.

As the cuff is deflated, sounds first occur at the systolic blood pressure; the sounds suddenly become faint at the diastolic blood pressure.

If a blood pressure is reported as “142 over 95,” what are the diastolic, systolic, and pulse pressures? Does this person have hypertension as defined on page 825?

18. Where may the pulse be felt?
19. What do tachycardia and bradycardia mean?
20. How are systolic and diastolic blood pressures measured with a sphygmomanometer?

### Shock and Homeostasis

#### Objectives

- Define shock, and describe the four types of shock.
- Explain how the body’s response to shock is regulated by negative feedback.

**Shock** is a failure of the cardiovascular system to deliver enough O₂ and nutrients to meet cellular metabolic needs. The causes of shock are many and varied, but all are characterized by inadequate blood flow to body tissues. With inadequate oxygen delivery, cells switch from aerobic to anaerobic production of ATP, and lactic acid accumulates in body fluids. If shock persists, cells and organs become damaged, and cells may die unless proper treatment begins quickly.

**Types of Shock**

Shock can be of four different types: (1) hypovolemic shock (hi-pō-vō-LĒ-mik; hypo- = low; -volemic = volume) due to decreased blood volume, (2) cardiogenic shock due to poor heart function, (3) vascular shock due to inappropriate vasodilation, and (4) obstructive shock due to obstruction of blood flow.

A common cause of hypovolemic shock is acute (sudden) hemorrhage. The blood loss may be external, as occurs in trauma, or internal, as in rupture of an aortic aneurysm. Loss of body fluids through excessive sweating, diarrhea, or vomiting also can cause hypovolemic shock. Other conditions—for instance, diabetes mellitus—may cause excessive loss of fluid in the urine. Sometimes, hypovolemic shock is due to inadequate intake of fluid. Whatever the cause, when the volume of body fluids falls, venous return to the heart declines, filling of the heart lessens, stroke volume decreases, and cardiac output decreases. Replacing fluid volume as quickly as possible is essential in managing hypovolemic shock.

In cardiogenic shock, the heart fails to pump adequately, most often because of a myocardial infarction (heart attack). Other causes of cardiogenic shock include poor perfusion of the heart (ischemia), heart valve problems, excessive preload or afterload, impaired contractility of heart muscle fibers, and arrhythmias.

Even with normal blood volume and cardiac output, shock may occur if blood pressure drops due to a decrease in systemic vascular resistance. A variety of conditions can cause inappropriate dilation of arterioles or venules. In anaphylactic shock, a severe allergic reaction—for example, to a bee sting—releases histamine and other mediators that cause vasodilation. In neurogenic shock, vasodilation may occur following trauma to the head that causes malfunction of the cardiovascular center in the medulla. Shock stemming from certain bacterial toxins that produce vasodilation is termed septic shock. In the United States,
septic shock causes more than 100,000 deaths per year and is the most common cause of death in hospital critical care units. Obstructive shock occurs when blood flow through a portion of the circulation is blocked. The most common cause is pulmonary embolism, a blood clot lodged in a blood vessel of the lungs.

**Homeostatic Responses to Shock**

The major mechanisms of compensation in shock are **negative feedback systems** that work to return cardiac output and arterial blood pressure to normal. When shock is mild, compensation by homeostatic mechanisms prevents serious damage. In an otherwise healthy person, compensatory mechanisms can maintain

---

**Figure 21.16** Negative feedback systems that can restore normal blood pressure during hypovolemic shock.

Homeostatic mechanisms can compensate for an acute blood loss of as much as 10% of total blood volume.

Does almost-normal blood pressure in a person who has lost blood indicate that the patient’s tissues are receiving adequate perfusion (blood flow)?
adequate blood flow and blood pressure despite an acute blood loss of as much as 10% of total volume. Figure 21.16 on page 782 shows several of the negative feedback systems that respond to hypovolemic shock.

1. **Activation of the renin–angiotensin–aldosterone system.** Decreased blood flow to the kidneys causes the kidneys to secrete renin and initiates the renin–angiotensin–aldosterone system (see Figure 18.16 on page 667). Recall that angiotensin II causes vasoconstriction and stimulates the adrenal cortex to secrete aldosterone, a hormone that increases reabsorption of Na⁺ and water by the kidneys. The increases in systemic vascular resistance and blood volume help raise blood pressure.

2. **Secretion of antidiuretic hormone.** In response to decreased blood pressure, the posterior pituitary releases more antidiuretic hormone (ADH). ADH enhances water reabsorption by the kidneys, which conserves remaining blood volume. It also causes vasoconstriction, which increases systemic vascular resistance. (See Figure 18.9 on page 657.)

3. **Activation of the sympathetic division of the ANS.** As blood pressure decreases, the aortic and carotid baroreceptors initiate powerful sympathetic responses throughout the body. One result is marked vasoconstriction of arterioles and veins of the skin, kidneys, and other abdominal viscera. (Vasoconstriction does not occur in the brain or heart.) The constriction of arterioles increases systemic vascular resistance, and the constriction of veins increases venous return. Both effects help maintain an adequate blood pressure. Sympathetic stimulation also increases heart rate and contractility and increases secretion of epinephrine and norepinephrine by the adrenal medulla. These hormones intensify vasoconstriction and increase heart rate and contractility, all of which help raise blood pressure.

4. **Release of local vasodilators.** In response to hypoxia, cells liberate vasodilators—including K⁺, H⁺, lactic acid, adenosine, and nitric oxide—that dilate arterioles and relax precapillary sphincters. Such vasodilation increases local blood flow and may restore O₂ level to normal in part of the body. However, vasodilation also has the potentially harmful effect of decreasing systemic vascular resistance and thus lowering the blood pressure.

If blood volume drops more than 10–20%, or if the heart cannot bring blood pressure up sufficiently, compensatory mechanisms may fail to maintain adequate blood flow to tissues. At this point, shock becomes life-threatening as damaged cells start to die.

### Signs and Symptoms of Shock

Even though the signs and symptoms of shock vary with the severity of the condition, most can be predicted in light of the responses generated by the negative feedback systems that attempt to correct the problem. Among the signs and symptoms of shock are the following:

- Systolic blood pressure is lower than 90 mmHg.
- Resting heart rate is rapid due to sympathetic stimulation and increased blood levels of epinephrine and norepinephrine.
- Pulse is weak and rapid due to reduced cardiac output and fast heart rate.
- Skin is cool, pale, and clammy due to sympathetic constriction of skin blood vessels and sympathetic stimulation of sweating.
- Mental state is altered due to reduced oxygen supply to the brain.
- Urine formation is reduced due to increased levels of aldosterone and antidiuretic hormone (ADH).
- The person is thirsty due to loss of extracellular fluid.
- The pH of blood is low (acidosis) due to buildup of lactic acid.
- The person may have nausea because of impaired blood flow to the digestive organs from sympathetic vasoconstriction.

### CHECKPOINT

21. Which symptoms of hypovolemic shock relate to actual body fluid loss, and which relate to the negative feedback systems that attempt to maintain blood pressure and blood flow?

22. Describe the types of shock and their causes and how a person in hypovolemic shock should be treated.

### CIRCULATORY ROUTES

#### OBJECTIVES

- Describe and compare the major routes that blood takes through various regions of the body.

Blood vessels are organized into **circulatory routes** that carry blood to specific organs in the body (Figure 21.17). The routes are parallel—in most cases a portion of the cardiac output flows separately to each tissue of the body, so that each organ receives its own supply of freshly oxygenated blood. The two main circulatory routes, the systemic circulation and pulmonary circulation, differ in two important ways. First, blood in the pulmonary circulation need not be pumped as far as blood in the systemic circulation. Second, compared to systemic arteries, pulmonary arteries have larger diameters, thinner walls, and less elastic tissue. As a result, the resistance to pulmonary blood flow is very low, which means that less pressure is needed to move blood through the lungs. The peak systolic pressure in the right ventricle is only 20% of that in the left ventricle.

#### The Systemic Circulation

The **systemic circulation** includes the arteries and arterioles that carry oxygenated blood from the left ventricle to systemic capillaries, plus the veins and venules that return deoxygenated blood to the right atrium. Blood leaving the aorta and flowing through the systemic arteries is a bright red color. As blood flows through capillaries, it loses some of its oxygen and picks up carbon dioxide, becoming a dark red color. All systemic arteries branch from the aorta. Completing the circuit, all the veins of
the systemic circulation drain into the superior vena cava, the inferior vena cava, or the coronary sinus, which in turn empty into the right atrium. The bronchial arteries, which carry nutrients to the lungs, also are part of the systemic circulation.

Exhibits 21.1–21.12 and Figures 21.18–21.27 describe the main arteries and veins of the systemic circulation. The blood vessels are organized in the exhibits according to body regions. Figure 21.18a provides an overview of the major arteries, and Figure 21.23 provides an overview of the major veins. As you study the various blood vessels in the exhibits, refer to these two figures to see the relationships of the blood vessels under consideration to other regions of the body.
The aorta (= to lift up) is the largest artery of the body, with a diameter of 2–3 cm (about 1 in.). Its four principal divisions are the ascending aorta, arch of the aorta, thoracic aorta, and abdominal aorta (Figure 21.18). The portion of the aorta that emerges from the left ventricle posterior to the pulmonary trunk is the **ascending aorta**. The beginning of the aorta contains the aortic valve (see Figure 20.4a on page 723). The ascending aorta gives off two coronary artery branches that supply the myocardium of the heart. Then the ascending aorta arches to the left, forming the **arch of the aorta**, which descends and ends at the level of the intervertebral disc between the fourth and fifth thoracic vertebrae. As the aorta continues to descend, it lies close to the vertebral bodies, passes through the aortic hiatus of the diaphragm, and divides at the level of the fourth lumbar vertebra into two **common iliac arteries**, which carry blood to the lower limbs. The section of the aorta between the arch of the aorta and the diaphragm is called the **thoracic aorta**; the section between the diaphragm and the common iliac arteries is the **abdominal aorta**. Each division of the aorta gives off arteries that branch into distributing arteries that lead to various organs. Within the organs, the arteries divide into arterioles and then into capillaries that service the systemic tissues (all tissues except the alveoli of the lungs).

**CHECKPOINT**

What general regions do each of the four principal divisions of the aorta supply?
Figure 21.18  Aorta and its principal branches.

All systemic arteries branch from the aorta.
What are the four subdivisions of the aorta?
EXHIBIT 21.2 Ascending Aorta

**OBJECTIVE**
- Identify the two primary arterial branches of the ascending aorta.

The **ascending aorta** is about 5 cm (2 in.) in length and begins at the aortic valve (see Figure 20.8 on page 729). It is directed superiorly, slightly anteriorly, and to the right. It ends at the level of the sternal angle, where it becomes the arch of the aorta. The beginning of the ascending aorta is posterior to the pulmonary trunk and right auricle; the right pulmonary artery is posterior to it. At its origin, the ascending aorta contains three dilations called aortic sinuses. Two of these, the right and left sinuses, give rise to the right and left coronary arteries, respectively.

The right and left **coronary arteries** (coron- = crown) arise from the ascending aorta just superior to the aortic valve (see Figure 20.8 on page 729). They form a crownlike ring around the heart, giving off branches to the atrial and ventricular myocardium. The **posterior interventricular branch** (in-ter-ven-TRIK-û-lar; inter- = between) of the right coronary artery supplies both ventricles, and the **marginal branch** supplies the right ventricle. The **anterior interventricular branch**, also known as the **left anterior descending (LAD) branch**, of the left coronary artery supplies both ventricles, and the **circumflex branch** (SER-kum-flex; circum- = around; -flex = to bend) supplies the left atrium and left ventricle.

**CHECKPOINT**
Which branches of the coronary arteries supply the left ventricle? Why does the left ventricle have such an extensive arterial blood supply?
The arch of the aorta is 4–5 cm (almost 2 in.) in length and is the continuation of the ascending aorta. It emerges from the pericardium posterior to the sternum at the level of the sternal angle (Figure 21.19). The arch of the aorta is directed superiorly and posteriorly to the left and then inferiorly; it ends at the intervertebral disc between the fourth and fifth thoracic vertebrae, where it becomes the thoracic aorta. Three major arteries branch from the superior aspect of the arch of the aorta: the brachiocephalic trunk, the left common carotid, and the left subclavian.

<table>
<thead>
<tr>
<th>BRANCH</th>
<th>DESCRIPTION AND REGION SUPPLIED</th>
</tr>
</thead>
<tbody>
<tr>
<td>BRACHIOCEPHALIC TRUNK</td>
<td>The brachiocephalic trunk divides to form the right subclavian artery and right common carotid artery (Figure 21.19a).</td>
</tr>
<tr>
<td>Right subclavian artery (sub-KLĂ-vē-an)</td>
<td>The right subclavian artery extends from the brachiocephalic trunk to the first rib and then passes into the armpit (axilla). The general distribution of the artery is to the brain and spinal cord, neck, shoulder, thoracic viscera and wall, and scapular muscles.</td>
</tr>
<tr>
<td>Internal thoracic or mammary artery (thor-AS-ik; thorac- = chest)</td>
<td>The internal thoracic artery arises from the first part of the subclavian artery and descends posterior to the costal cartilages of the superior six ribs. It terminates at the sixth intercostal space. It supplies the anterior thoracic wall and structures in the mediastinum. In coronary artery bypass grafting, if only a single vessel is obstructed, the internal thoracic (usually the left) is used to create the bypass. The upper end of the artery is left attached to the subclavian artery and the cut end is connected to the coronary artery at a point distal to the blockage. The lower end of the internal thoracic artery is tied off. Artery grafts are preferred over vein grafts because arteries can withstand the greater pressure of blood flowing through coronary arteries and are less likely to become obstructed over time.</td>
</tr>
<tr>
<td>Vertebral artery (VER-te-bral)</td>
<td>Before passing into the axilla, the right subclavian artery gives off a major branch to the brain called the right vertebral artery (Figure 21.19b). The right vertebral artery passes through the foramina of the transverse processes of the sixth through first cervical vertebrae and enters the skull through the foramen magnum to reach the inferior surface of the brain. Here it unites with the left vertebral artery to form the basilar (BAS-i-lar) artery. The vertebral artery supplies the posterior portion of the brain with blood. The basilar artery passes along the midline of the anterior aspect of the brain stem. It gives off several branches (posterior cerebral and cerebellar arteries) that supply the cerebellum and pons of the brain and the inner ear.</td>
</tr>
<tr>
<td>Axillary artery (AK-sil-ār-ē = armpit)</td>
<td>The continuation of the subclavian artery into the axilla is called the axillary artery. (Note that the right subclavian artery, which passes deep to the clavicle, is a good example of the practice of giving the same vessel different names as it passes through different regions.) Its general distribution is the shoulder, thoracic and scapular muscles, and humerus.</td>
</tr>
<tr>
<td>Brachial artery (BRĀ-kĕ-al = arm)</td>
<td>The brachial artery is the continuation of the axillary artery into the arm. The brachial artery provides the main blood supply to the arm and is superficial and palpable along its course. It begins at the tendon of the teres major muscle and ends just distal to the bend of the elbow. At first, the brachial artery is medial to the humerus, but as it descends it gradually curves laterally and passes through the cubital fossa, a triangular depression anterior to the elbow where you can easily detect the pulse of the brachial artery and listen to the various sounds when taking a person’s blood pressure. Just distal to the bend in the elbow, the brachial artery divides into the radial artery and ulnar artery. Blood pressure is usually measured in the brachial artery. In order to control hemorrhage, the best place to compress the brachial artery is near the middle of the arm.</td>
</tr>
<tr>
<td>Radial artery (RĀ-dē-al = radius)</td>
<td>The radial artery is the smaller branch and is a direct continuation of the brachial artery. It passes along the lateral (radial) aspect of the forearm and then through the wrist and hand, supplying these structures with blood. At the wrist, the radial artery makes contact with the distal end of the radius, where it is covered only by fascia and skin. Because of its superficial location at this point, it is a common site for measuring the radial pulse.</td>
</tr>
<tr>
<td>Ulnar artery (UL-nar = ulna)</td>
<td>The ulnar artery, the larger branch of the brachial artery, passes along the medial (ulnar) aspect of the forearm and then into the wrist and hand, supplying these structures with blood. In the palm, branches of the radial and ulnar arteries anastomose to form the superficial palmar arch and the deep palmar arch.</td>
</tr>
<tr>
<td>Superficial palmar arch (palma = palm)</td>
<td>The superficial palmar arch is formed mainly by the ulnar artery, with a contribution from a branch of the radial artery. The arch is superficial to the long flexor tendons of the fingers and extends across the palm at the bases of the metacarpals. It gives rise to common palmar digital arteries, which supply the palm. Each divides into a pair of proper palmar digital arteries, which supply the fingers.</td>
</tr>
<tr>
<td>Deep palmar arch</td>
<td>Mainly the radial artery forms the deep palmar arch, with a contribution from a branch of the ulnar artery. The arch is deep to the long flexor tendons of the fingers and extends across the palm, just distal to the bases of the metacarpals. Arising from the deep palmar arch are palmar metacarpal arteries, which supply the palm and anastomose with the common palmar digital arteries of the superficial palmar arch.</td>
</tr>
<tr>
<td>Right common carotid artery</td>
<td>The right common carotid artery begins at the bifurcation (division into two branches) of the brachiocephalic trunk, posterior to the right sternoclavicular joint, and passes superiorly in the neck to supply structures in the head (Figure 21.19b). At the superior border of the larynx (voice box), it divides into the right external and right internal carotid arteries. Pulse may be detected in the common carotid artery, just lateral to the larynx. It is convenient to detect a carotid pulse when exercising or when administering cardiopulmonary resuscitation.</td>
</tr>
<tr>
<td>External carotid artery</td>
<td>The external carotid artery begins at the superior border of the larynx and terminates near the temporomandibular joint of the parotid gland, where it divides into two branches: the superficial temporal and maxillary arteries. The carotid pulse can be detected in the external carotid artery just anterior to the sternocleidomastoid muscle at the superior border of the larynx. The general distribution of the external carotid artery is to structures external to the skull.</td>
</tr>
</tbody>
</table>
The internal carotid artery has no branches in the neck and supplies structures internal to the skull. It enters the cranial cavity through the carotid foramen in the temporal bone. The internal carotid artery supplies blood to the eyeball and other orbital structures, ear, most of the cerebrum of the brain, pituitary gland, and external nose. The terminal branches of the internal carotid artery are the anterior cerebral artery, which supplies most of the medial surface of the cerebrum and deep masses of gray matter within the cerebrum, and the middle cerebral artery, which supplies most of the lateral surface of the cerebrum (Figure 21.19c). Inside the cranium, anastomoses of the left and right internal carotid arteries along with the basilar artery form an arrangement of blood vessels at the base of the brain near the hypophyseal fossa called the cerebral arterial circle (circle of Willis). From this circle (Figure 21.19c) arise arteries supplying most of the brain. Essentially, the cerebral arterial circle is formed by the union of the anterior cerebral arteries (branches of internal carotids) and posterior cerebral arteries (branches of basilar artery). The posterior cerebral arteries supply the inferolateral surface of the temporal lobe and lateral and medial
surfaces of the occipital lobe of the cerebrum, deep masses of gray matter within the cerebrum, and midbrain. The posterior cerebral arteries are connected with the internal carotid arteries by the posterior communicating arteries. The anterior communicating arteries connect the anterior cerebral arteries. The internal carotid arteries are also considered part of the cerebral arterial circle. The functions of the cerebral arterial circle are to equalize blood pressure to the brain and provide alternate routes for blood flow to the brain, should the arteries become damaged.

**Figure 21.19 Arch of the aorta and its branches.** Note in (c) the arteries that constitute the cerebral arterial circle (circle of Willis).

The arch of the aorta ends at the level of the intervertebral disc between the fourth and fifth thoracic vertebrae.
The first and largest branch from the arch of the aorta is the **brachiocephalic trunk** (brā'-kē-o-se-FAL-ik; *brachio-* = arm; *cephalic* = head). It extends superiorly, bending slightly to the right, and divides at the right sternoclavicular joint to form the right subclavian artery and right common carotid artery. The second branch from the arch of the aorta is the **left common carotid artery** (ka-ROT-id), which divides into the same branches with the same names as the right common carotid artery. The third branch from the arch of the aorta is the **left subclavian artery** (sub-KLA-vē-an), which distributes blood to the left vertebral artery and vessels of the left upper limb. Arteries branching from the left subclavian artery are similar in distribution and name to those branching from the right subclavian artery. The following description focuses on the principal arteries originating from the brachiocephalic trunk.

**CHECKPOINT**

What general regions do the arteries that arise from the arch of the aorta supply?

What are the three major branches of the arch of the aorta, in order of their origination?
### OBJECTIVE
- Identify the visceral and parietal branches of the thoracic aorta.

The **thoracic aorta** is about 20 cm (8 in.) long and is a continuation of the arch of the aorta (Figure 21.20). It begins at the level of the intervertebral disc between the fourth and fifth thoracic vertebrae, where it lies to the left of the vertebral column. As it descends, it moves closer to the midline and extends through an opening in the diaphragm (aortic hiatus), which is located anterior to the vertebral column at the level of the intervertebral disc between the twelfth thoracic and first lumbar vertebrae.

Along its course, the thoracic aorta sends off numerous small arteries, **visceral branches** to viscera, and **parietal branches** to body wall structures.

### CHECKPOINT

**EXHIBIT 21.4 CONTINUES**

**EXHIBIT 21.4**

**Thoracic Aorta**
**Figure 21.20** Thoracic aorta and abdominal aorta and their principal branches.

The thoracic aorta is the continuation of the ascending aorta.

Where does the thoracic aorta begin?
OBJECTIVE

- Identify the visceral and parietal branches of the abdominal aorta.

The **abdominal aorta** is the continuation of the thoracic aorta (Figure 21.21 on pages 797–798). It begins at the aortic hiatus in the diaphragm and ends at about the level of the fourth lumbar vertebra, where it divides into the right and left common iliac arteries. The abdominal aorta lies anterior to the vertebral column.

As with the thoracic aorta, the abdominal aorta gives off **visceral and parietal branches**. The unpaired visceral branches arise from the anterior surface of the aorta and include the **celiac trunk** and the **superior mesenteric and inferior mesenteric arteries** (see Figure 21.20).

### Unpaired Visceral Branches

<table>
<thead>
<tr>
<th>Branch</th>
<th>Description and Region Supplied</th>
</tr>
</thead>
<tbody>
<tr>
<td>Celiac trunk (SE-é-ak)</td>
<td>The celiac trunk (artery) is the first visceral branch from the aorta inferior to the diaphragm, at about the level of the twelfth thoracic vertebra (Figure 21.21a). Almost immediately the celiac trunk divides into three branches: the left gastric, splenic, and common hepatic arteries (Figure 21.21a).</td>
</tr>
<tr>
<td>Superior mesenteric artery (MES-en-ter'-ik; meso = middle; enteric = pertaining to the intestines)</td>
<td>The superior mesenteric artery (Figure 21.21b) arises from the anterior surface of the abdominal aorta about 1 cm inferior to the celiac trunk at the level of the first lumbar vertebra. It extends inferiorly and anteriorly and between the layers of mesentry, which is a portion of the peritoneum that attaches the small intestine to the posterior abdominal wall. It anastomoses extensively and has five branches:</td>
</tr>
<tr>
<td>Inferior mesenteric artery</td>
<td>The inferior mesenteric artery (Figure 21.21c) arises from the anterior aspect of the abdominal aorta at the level of the third lumbar vertebra and then passes inferiorly to the left of the aorta. It anastomoses extensively and has three branches:</td>
</tr>
<tr>
<td>Suprenal arteries (soo'-pra-RÉ-nal; supra- = above; ren- = kidney)</td>
<td>Although there are three pairs of suprenal (adrenal) arteries that supply the adrenal (suprenal) glands (superior, middle, and inferior), only the middle pair originates directly from the abdominal aorta (see Figure 21.20). The middle suprenal arteries arise at the level of the first lumbar vertebra at or superior to the renal arteries. The superior suprenal arteries arise from the inferior phrenic artery, and the inferior suprenal arteries originate from the renal arteries.</td>
</tr>
<tr>
<td>Renal arteries (RÉ-nal; ren- = kidney)</td>
<td>The right and left renal arteries usually arise from the lateral aspects of the abdominal aorta at the superior border of the second lumbar vertebra, about 1 cm inferior to the superior mesenteric artery (see Figure 21.20). The right renal artery, which is longer than the left, arises slightly lower than the left and passes posterior to the right renal vein and inferior vena cava. The left renal artery is posterior to the left renal vein and is crossed by the inferior mesenteric vein. The renal arteries carry blood to the kidneys, adrenal (suprenal) glands, and ureters. Their distribution within the kidneys is discussed in Chapter 26.</td>
</tr>
<tr>
<td>Gonadal arteries (gô-NAD-al; gon- = seed)</td>
<td>The gonadal arteries arise from the abdominal aorta at the level of the second lumbar vertebra just inferior to the renal arteries (see Figure 21.20). In males, the gonadal arteries are specifically referred to as the testicular arteries. They pass through the inguinal canal and supply the testes, epididymis, and ureters. In females, the gonadal arteries are called the ovarian arteries. They are much shorter than the testicular arteries and supply the ovaries, uterine (fallopian) tubes, and ureters.</td>
</tr>
</tbody>
</table>
The paired visceral branches arise from the lateral surfaces of the aorta and include the suprarenal, renal, and gonadal arteries. The unpaired parietal branch is the median sacral artery. The paired parietal branches arise from the posterolateral surfaces of the aorta and include the inferior phrenic and lumbar arteries.

### CHECKPOINT
Name the paired visceral and parietal branches and the unpaired visceral and parietal branches of the abdominal aorta, and indicate the general regions they supply.

#### UNPAIRED PARIETAL BRANCH
- **Median sacral artery**
  - (SA-kral = pertaining to the sacrum)
  - The median sacral artery arises from the posterior surface of the abdominal aorta about 1 cm superior to the bifurcation (division into two branches) of the aorta into the right and left common iliac arteries (see Figure 21.20). The median sacral artery supplies the sacrum and coccyx.

#### PAIRED PARIETAL BRANCHES
- **Inferior phrenic arteries**
  - (FREN-ik = pertaining to the diaphragm)
- **Lumbar arteries**
  - (LUM-bar = pertaining to the loin)
  - The inferior phrenic arteries are the first paired branches of the abdominal aorta, immediately superior to the origin of the celiac trunk (see Figure 21.20). (They may also arise from the renal arteries.) The inferior phrenic arteries are distributed to the inferior surface of the diaphragm and adrenal (suprarenal) glands.
  - The four pairs of lumbar arteries arise from the posterolateral surface of the abdominal aorta (see Figure 21.20). They supply the lumbar vertebrae, spinal cord and its meninges, and the muscles and skin of the lumbar region of the back.

### SCHEME OF DISTRIBUTION

</thead>
<tbody>
<tr>
<td>COMMON ILIAC ARTERIES</td>
<td>At about the level of the fourth lumbar vertebra, the abdominal aorta divides into the right and left common iliac arteries, the terminal branches of the abdominal aorta. Each passes inferiorly about 5 cm (2 in.) and gives rise to two branches: internal iliac and external iliac arteries. The general distribution of the common iliac arteries is to the pelvis, external genitals, and lower limbs.</td>
</tr>
<tr>
<td>Internal iliac arteries</td>
<td>The internal iliac (hypogastric) arteries are the primary arteries of the pelvis. They begin at the bifurcation (division into two branches) of the common iliac arteries anterior to the sacroiliac joint at the level of the lumbosacral intervertebral disc. They pass posteromedially as they descend in the pelvis and divide into anterior and posterior divisions. The general distribution of the internal iliac arteries is to the pelvis, buttocks, external genitals, and thigh.</td>
</tr>
<tr>
<td>External iliac arteries</td>
<td>The external iliac arteries are larger than the internal iliac arteries. Like the internal iliac arteries, they begin at the bifurcation of the common iliac arteries. They descend along the medial border of the psoas major muscles following the pelvic brim, pass posterior to the midportion of the inguinal ligaments, and become the femoral arteries. The general distribution of the external iliac arteries is to the lower limbs. Specifically, branches of the external iliac arteries supply the muscles of the anterior abdominal wall, the cremaster muscle in males and the round ligament of the uterus in females, and the lower limbs.</td>
</tr>
<tr>
<td>Femoral arteries</td>
<td>The femoral arteries descend along the anteromedial aspects of the thighs to the junction of the middle and lower third of the thighs. Here they pass through an opening in the tendon of the adductor magnus muscle, then emerge posterior to the femurs as the popliteal arteries. A pulse may be felt in the femoral artery just inferior to the inguinal ligament. Recall from Chapter 11 that the femoral artery, along with the femoral vein and nerve and deep inguinal lymph nodes, are located in the femoral triangle (see Figure 11.20a on page 395). The general distribution of the femoral arteries is to the lower abdominal wall, groin, external genitals, and muscles of the thigh. A major branch of the femoral artery, the deep artery of the thigh (deep femoral), supplies most of the muscles of the thigh: quadriceps femoris, adductors, and hamstrings.</td>
</tr>
<tr>
<td>Popliteal arteries</td>
<td>The popliteal arteries are the continuation of the femoral arteries through the popliteal fossa (space behind the knee). They descend to the inferior border of the popliteus muscles, where they divide into the anterior and posterior tibial arteries. A pulse may be detected in the popliteal arteries. In addition to supplying the adductor magnus and hamstring muscles and the skin on the posterior aspect of the legs, branches of the popliteal arteries also supply the gastrocnemius, soleus, and plantaris muscles of the calf, knee joint, femur, patella, and fibula.</td>
</tr>
<tr>
<td>Anterior tibial arteries</td>
<td>The anterior tibial arteries descend from the bifurcation of the popliteal arteries. They are smaller than the posterior tibial arteries. The anterior tibial arteries descend through the anterior muscular compartment of the leg. They pass through the interosseous membrane that connects the tibia and fibula, lateral to the tibia. The anterior tibial arteries supply the knee joints, anterior compartment muscles of the legs, skin over the anterior aspects of the legs, and ankle joints. At the ankles, the anterior tibial arteries become the dorsal arteries of the foot (dorsalis pedis arteries). A pulse in this artery may be taken to evaluate the peripheral vascular system. The dorsal arteries of the foot supply the muscles, skin, and joints on the dorsal aspects of the feet. On the dorsum of the feet, the dorsal arteries of the foot give off a transverse branch at the first (medial) cuneiform bone called the arcuate arteries (arcuatus = bowed) that run laterally over the bases of the metatarsals. From the arcuate arteries branch the dorsal metatarsal arteries, which supply the feet. The dorsal metatarsal arteries terminate by dividing into the dorsal digital arteries, which supply the toes.</td>
</tr>
<tr>
<td>Posterior tibial arteries</td>
<td>The posterior tibial arteries, the direct continuations of the popliteal arteries, descend from the bifurcation of the popliteal arteries. They pass down the posterior muscular compartment of the legs posterior to the medial malleolus of the tibia. They terminate by dividing into the medial and lateral plantar arteries. Their general distribution is to the muscles, bones, and joints of the leg and foot. Major branches of the posterior tibial arteries are the fibular (peroneal) arteries, which supply the fibularis, soleus, tibialis posterior, and flexor hallucis muscles. They also supply the fibula, tarsus, and lateral aspect of the heel. The bifurcation of the posterior tibial artery into the medial and lateral plantar arteries occurs deep to the flexor retinaculum on the medial side of the feet. The medial plantar arteries (PLAN-tar = sole) supply the abductor hallucis and flexor digitorum brevis muscles and the toes. The lateral plantar arteries unite with a branch of the dorsal arteries of the foot to form the plantar arch. The arch begins at the base of the fifth metatarsal and extends medially across the metacarpals. As the arch crosses the foot, it gives off plantar metatarsal arteries, which supply the feet. These terminate by dividing into plantar digital arteries, which supply the toes.</td>
</tr>

CHECKPOINT
What general regions do the internal and external iliac arteries supply?
Arteries of the Pelvis and Lower Limbs

**SCHEME OF DISTRIBUTION**

- **Abdominal aorta**
  - Right common iliac
    - Right external iliac
      - Right femoral
        - Right deep artery of the thigh (deep peroneal)
      - Right popliteal
        - Right anterior tibial
          - Right dorsal artery of foot (dorsalis pedis)
            - Right arcuate
              - Right dorsal metatarsal
                - Right dorsal digital
                  - Right plantar arch
                    - Right plantar metatarsal
                      - Right plantar digital
    - Right internal iliac

- Left common iliac
  (gives rise to same branches as right common iliac, except that arteries are labeled left instead of right)
Figure 21.22 Arteries of the pelvis and right lower limb.

The internal iliac arteries carry most of the blood supply to the pelvic viscera and wall.

At what point does the abdominal aorta divide into the common iliac arteries?
they connect in irregular networks in which many tributaries merge to form a large vein. Although only one systemic artery, the aorta, takes oxygenated blood away from the heart (left ventricle), three systemic veins, the coronary sinus, superior vena cava, and inferior vena cava, return deoxygenated blood to the heart (right atrium) (Figure 21.23). The coronary sinus receives blood from the cardiac veins; the superior vena cava receives blood from other veins superior to the diaphragm, except the air sacs (alveoli) of the lungs; the inferior vena cava receives blood from veins inferior to the diaphragm.

**CHECKPOINT**

What are the three tributaries of the coronary sinus?

---

<table>
<thead>
<tr>
<th>VEIN</th>
<th>DESCRIPTION AND REGION DRAINED</th>
</tr>
</thead>
<tbody>
<tr>
<td>Coronary sinus</td>
<td>The <strong>coronary sinus</strong> is the main vein of the heart; it receives almost all venous blood from the myocardium. It is located in the coronary sulcus (see Figure 20.3 on page 722) and opens into the right atrium between the orifice of the inferior vena cava and the tricuspid valve. It is a wide venous channel into which three veins drain. It receives the <strong>great cardiac vein</strong> (in the anterior interventricular sulcus) into its left end, and the <strong>middle cardiac vein</strong> (in the posterior interventricular sulcus) and the <strong>small cardiac vein</strong> into its right end. Several <strong>anterior cardiac veins</strong> drain directly into the right atrium.</td>
</tr>
<tr>
<td>Superior vena cava (SVC)</td>
<td>The <strong>superior vena cava</strong> is about 7.5 cm (3 in.) long and 2 cm (1 in.) in diameter and empties its blood into the superior part of the right atrium. It begins posterior to the right first costal cartilage by the union of the right and left brachiocephalic veins and ends at the level of the right third costal cartilage, where it enters the right atrium. The SVC drains the head, neck, chest, and free upper limbs.</td>
</tr>
<tr>
<td>Inferior vena cava (IVC)</td>
<td>The <strong>inferior vena cava</strong> is the largest vein in the body, about 3.5 cm (1.4 in.) in diameter. It begins anterior to the fifth lumbar vertebra by the union of the common iliac veins, ascends behind the peritoneum to the right of the midline, pierces the caval opening of the diaphragm at the level of the eighth thoracic vertebra, and enters the inferior part of the right atrium. The IVC drains the abdomen, pelvis, and free lower limbs. The inferior vena cava is commonly compressed during the later stages of pregnancy by the enlarging uterus, producing edema of the ankles and feet and temporary varicose veins.</td>
</tr>
</tbody>
</table>
Figure 21.23 Principal veins.

Deoxygenated blood returns to the heart via the superior vena cava, inferior vena cava, and the coronary sinus.

Which general regions of the body are drained by the superior vena cava and the inferior vena cava?
**OBJECTIVE**

- Identify the three major veins that drain blood from the head.

Most blood draining from the head passes into three pairs of veins: the **internal jugular**, **external jugular**, and **vertebral veins** (Figure 21.24). Within the brain, all veins drain into dural venous sinuses and then into the internal jugular veins. Dural venous sinuses are endothelial-lined venous channels between layers of the cranial dura mater.

**CHECKPOINT**

Which general areas are drained by the internal jugular, external jugular, and vertebral veins?

<table>
<thead>
<tr>
<th>VEIN</th>
<th>DESCRIPTION AND REGION DRAINED</th>
</tr>
</thead>
<tbody>
<tr>
<td>Internal jugular veins</td>
<td>The flow of blood from the dural venous sinuses into the internal jugular veins is as follows (Figure 21.24): The <strong>superior sagittal sinus</strong> (SAJ-i-tal = straight) begins at the frontal bone, where it receives a vein from the nasal cavity, and passes posteriorly to the occipital bone. Along its course, it receives blood from the superior, medial, and lateral aspects of the cerebral hemispheres, meninges, and cranial bones. The superior sagittal sinus usually turns to the right and drains into the right transverse sinus. The <strong>inferior sagittal sinus</strong> is much smaller than the superior sagittal sinus; it begins posterior to the attachment of the falx cerebri and receives the great cerebral vein to become the straight sinus. The great cerebral vein drains the deeper parts of the brain. Along its course the inferior sagittal sinus also receives tributaries from the superior and medial aspects of the cerebral hemispheres. The <strong>straight sinus</strong> runs in the tentorium cerebelli and is formed by the union of the inferior sagittal sinus and the great cerebral vein. The straight sinus also receives blood from the cerebellum and usually drains into the left transverse sinus. The <strong>transverse sinuses</strong> begin near the occipital bone, pass laterally and anteriorly, and become the sigmoid sinuses near the temporal bone. The transverse sinuses receive blood from the cerebrum, cerebellum, and cranial bones. The <strong>sigmoid sinuses</strong> (SIG-moyd = S-shaped) are located along the temporal bone. They pass through the jugular foramina, where they terminate in the internal jugular veins. The sigmoid sinuses drain the transverse sinuses. The <strong>cavernous sinuses</strong> (KA-V-er-nus = cavelike) are located on either side of the sphenoid bone. They receive blood from the ophthalmic veins from the orbits, and from the cerebral veins from the cerebral hemispheres. They ultimately empty into the transverse sinuses and internal jugular veins. The cavernous sinuses are unique because they have nerves and a major blood vessel passing through them on their way to the orbit and face. The oculomotor (III) nerve, trochlear (IV) nerve, and ophthalmic and maxillary branches of the trigeminal (V) nerve as well as the internal carotid arteries pass through the cavernous sinuses. The right and left <strong>internal jugular veins</strong> pass inferiorly on either side of the neck lateral to the internal carotid and common carotid arteries. They then unite with the subclavian veins posterior to the clavicles at the sternoclavicular joints to form the right and left brachiocephalic veins (bra-kè-ò-šé-fal-ik; brachio-= arm; cephal-= head). From here blood flows into the superior vena cava. The general structures drained by the internal jugular veins are the brain (through the dural venous sinuses), face, and neck. The right and left <strong>external jugular veins</strong> begin in the parotid glands near the angle of the mandible. They are superficial veins that descend through the neck across the sternocleidomastoid muscles. They terminate at a point opposite the middle of the clavicles, where they empty into the subclavian veins. The general structures drained by the external jugular veins are external to the cranium, such as the scalp and superficial and deep regions of the face. When venous pressure rises, for example, during heavy coughing or straining or in cases of heart failure, the external jugular veins become very prominent along the side of the neck. The right and left <strong>vertebral veins</strong> originate inferior to the occipital condyles. They descend through successive transverse foramina of the first six cervical vertebrae and emerge from the foramina of the sixth cervical vertebra to enter the brachiocephalic veins in the root of the neck. The vertebral veins drain deep structures in the neck such as the cervical vertebrae, cervical spinal cord, and some neck muscles.</td>
</tr>
</tbody>
</table>
Into which veins in the neck does all venous blood in the brain drain?
## Veins of the Upper Limbs

### Objective
- Identify the principal veins that drain the upper limbs.

Both superficial and deep veins return blood from the upper limbs to the heart (Figure 21.25 on page 808–809). **Superficial veins** are located just deep to the skin and are often visible. They anastomose extensively with one another and with deep veins, and they do not accompany arteries. **Superficial veins** are larger than deep veins and return most of the blood from the upper limbs. **Deep veins** are located deep in the body. They usually accompany arteries and have the same names as the corresponding arteries. Both superficial and deep veins have valves, but valves are more numerous in the deep veins.

### Vein Description and Region Drained

<table>
<thead>
<tr>
<th>Vein</th>
<th>Description and Region Drained</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Superficial</strong></td>
<td></td>
</tr>
<tr>
<td>Cephalic veins (se-FAL-ik = pertaining to the head)</td>
<td>The principal superficial veins that drain the upper limbs are the cephalic and basilic veins. They originate in the hand and convey blood from the smaller superficial veins into the axillary veins. The <strong>cephalic veins</strong> begin on the lateral aspect of the dorsal venous networks of the hands (dorsal venous arches), networks of veins on the dorsum of the hands formed by the dorsal metacarpal veins. These veins, in turn, drain the dorsal digital veins, which pass along the sides of the fingers. Following their formation from the dorsal venous networks of the hands, the cephalic veins arch around the radial side of the forearms to the anterior surface and ascend through the entire limbs along the anterolateral surface. The cephalic veins end where they join the axillary veins, just inferior to the clavicles. <strong>Accessory cephalic veins</strong> originate either from a venous plexus on the dorsum of the forearms or from the medial aspects of the dorsal venous networks of the hands, and unite with the cephalic veins just inferior to the elbow. The cephalic veins drain blood from the lateral aspect of the upper limbs.</td>
</tr>
<tr>
<td>Basilic veins (ba-SIL-ik = royal, of prime importance)</td>
<td>The <strong>basilic veins</strong> begin on the medial aspects of the dorsal venous networks of the hands and ascend along the posterosmedial surface of the forearm and anteromedial surface of the arm. They drain blood from the medial aspects of the upper limbs. Anterior to the elbow, the basilic veins are connected to the cephalic veins by the <strong>median cubital veins</strong> (cubital = pertaining to the elbow), which drain the forearm. If veins must be punctured for an injection, transfusion, or removal of a blood sample, the median cubital veins are preferred. After receiving the median cubital veins, the basilic veins continue ascending until they reach the middle of the arm. There they penetrate the tissues deeply and run alongside the brachial arteries until they join the brachial veins. As the basilic and brachial veins merge in the axillary area, they form the axillary veins.</td>
</tr>
<tr>
<td>Median antebrachial veins (an’-tê-BRA-ké-al; ante- = before, in front of; brachi- = arm)</td>
<td>The <strong>median antebrachial veins</strong> (median veins of the forearm) begin in the palmar venous plexuses, networks of veins on the palms. The plexuses drain the <strong>palmar digital veins</strong> in the fingers. The median antebrachial veins ascend anteriorly in the forearms to join the basilic or median cubital veins, sometimes both. They drain the palms and forearms.</td>
</tr>
<tr>
<td><strong>Deep</strong></td>
<td></td>
</tr>
<tr>
<td>Radial veins (RA-dé-al = pertaining to the radius)</td>
<td>The paired <strong>radial veins</strong> begin at the deep palmar venous arches. These arches drain the <strong>palmar metacarpal veins</strong> in the palms. The radial veins drain the lateral aspects of the forearms and pass along the radial arteries. Just inferior to the elbow joint, the radial veins unite with the ulnar veins to form the brachial veins.</td>
</tr>
<tr>
<td>Ulnar veins (UL-nar = pertaining to the ulna)</td>
<td>The paired <strong>ulnar veins</strong>, which are larger than the radial veins, begin at the superficial palmar venous arches. These arches drain the <strong>common palmar digital veins</strong> and the <strong>proper palmar digital veins</strong> in the fingers. The ulnar veins drain the medial aspect of the forearms, pass alongside the ulnar arteries, and join with the radial veins to form the brachial veins.</td>
</tr>
<tr>
<td>Brachial veins (BRÁ-ké-al; brachi- = arm)</td>
<td>The paired <strong>brachial veins</strong> accompany the brachial arteries. They drain the forearms, elbow joints, arms, and humerus. They pass superiorly and join with the basilic veins to form the axillary veins.</td>
</tr>
<tr>
<td>Axillary veins (AK-sil-ár-é; axilla = armpit)</td>
<td>The <strong>axillary veins</strong> ascend to the outer borders of the first ribs, where they become the subclavian veins. The axillary veins receive tributaries that correspond to the branches of the axillary arteries. The axillary veins drain the arms, axillae, and superolateral chest wall.</td>
</tr>
<tr>
<td>Subclavian veins (sub-KLÁ-vé-an; sub- = under; clavian = pertaining to the clavicle)</td>
<td>The <strong>subclavian veins</strong> are continuations of the axillary veins that terminate at the sternal end of the clavicles, where they unite with the internal jugular veins to form the brachiocephalic veins. The subclavian veins drain the arms, neck, and thoracic wall. The thoracic duct of the lymphatic system delivers lymph into the junction between the left subclavian and the left internal jugular veins. The right lymphatic duct delivers lymph into the junction between the right subclavian and right internal jugular veins. In a procedure called <strong>central line placement</strong>, the right subclavian vein is frequently used to administer nutrients and medication and measure venous pressure.</td>
</tr>
</tbody>
</table>
**CHECKPOINT**

Where do the cephalic, basilic, median antebrachial, radial, and ulnar veins originate?
Deep veins usually accompany arteries that have similar names.
From which vein in the upper limb is a blood sample often taken?
EXHIBIT 21.10
Veins of the Thorax

OBJECTIVE
- Identify the components of the azygos system of veins.

Although the brachiocephalic veins drain some portions of the thorax, most thoracic structures are drained by a network of veins, called the azygos system, that runs on either side of the vertebral column (Figure 21.26). The system consists of three veins—the azygos, hemiazygos, and accessory hemiazygos veins—that show considerable variation in origin, course, tributaries, anastomoses, and termination. Ultimately they empty into the superior vena cava.

CHECKPOINT
What is the importance of the azygos system relative to the inferior vena cava?

<table>
<thead>
<tr>
<th>VEIN</th>
<th>DESCRIPTION AND REGION DRAINED</th>
</tr>
</thead>
<tbody>
<tr>
<td>Brachiocephalic vein</td>
<td>The right and left brachiocephalic veins, formed by the union of the subclavian and internal jugular veins, drain blood from the head, neck, upper limbs, mammary glands, and superior thorax. The brachiocephalic veins unite to form the superior vena cava. Because the superior vena cava is to the right of the body’s midline, the left brachiocephalic vein is longer than the right. The right brachiocephalic vein is anterior and to the right of the brachiocephalic trunk. The left brachiocephalic vein is anterior to the brachiocephalic trunk, the left common carotid and left subclavian arteries, the trachea, the left vagus (X) nerve, and the phrenic nerve.</td>
</tr>
<tr>
<td>Azygos system</td>
<td>The azygos system, besides collecting blood from the thorax and abdominal wall, may serve as a bypass for the inferior vena cava that drains blood from the lower body. Several small veins directly link the azygos system with the inferior vena cava. Large veins that drain the lower limbs and abdomen conduct blood into the azygos system. If the inferior vena cava or hepatic portal vein becomes obstructed, the azygos system can return blood from the lower body to the superior vena cava.</td>
</tr>
<tr>
<td>Azygos vein</td>
<td>The azygos vein is anterior to the vertebral column, slightly to the right of the midline. It usually begins at the junction of the right ascending lumbar and right subcostal veins near the diaphragm. At the level of the fourth thoracic vertebra, it arches over the root of the right lung to end in the superior vena cava. Generally, the azygos vein drains the blood from the right side of the thoracic wall, thoracic viscera, and abdominal wall. Specifically, the azygos vein receives blood from most of the right posterior intercostal, hemiazygos, accessory hemiazygos, esophageal, mediastinal, pericardial, and bronchial veins.</td>
</tr>
<tr>
<td>Hemiazygos vein</td>
<td>The hemiazygos vein is anterior to the vertebral column and slightly to the left of the midline. It often begins at the junction of the left ascending lumbar and left subcostal veins. It terminates by joining the azygos vein at about the level of the ninth thoracic vertebra. Generally, the hemiazygos vein drains the left side of the thoracic wall, thoracic viscera, and abdominal wall. Specifically, the hemiazygos vein receives blood from the ninth through eleventh left posterior intercostal, esophageal, mediastinal, and sometimes the accessory hemiazygos veins.</td>
</tr>
<tr>
<td>Accessory hemiazygos vein</td>
<td>The accessory hemiazygos vein is also anterior to the vertebral column and to the left of the midline. It begins at the fourth or fifth intercostal space and descends from the fifth to the eighth thoracic vertebra or ends in the hemiazygos vein. It terminates by joining the azygos vein at about the level of the eighth thoracic vertebra. The accessory hemiazygos vein drains the left side of the thoracic wall. It receives blood from the fourth through eighth left posterior intercostal veins (the first through third left posterior intercostal veins open into the left brachiocephalic vein), left bronchial, and mediastinal veins.</td>
</tr>
</tbody>
</table>

SCHEME OF DRAINAGE
Figure 21.26 Principal veins of the thorax, abdomen, and pelvis.

Most thoracic structures are drained by the azygos system of veins.
Which vein returns blood from the abdominopelvic viscera to the heart?
OBJECTIVE

- Identify the principal veins that drain the abdomen and pelvis.

Blood from the abdominal and pelvic viscera and abdominal wall returns to the heart via the inferior vena cava. Many small veins enter the inferior vena cava. Most carry return flow from parietal branches of the abdominal aorta, and their names correspond to the names of the arteries (see also Figure 21.26 on page 811).

EXHIBIT 21.11

Veins of the Abdomen and Pelvis

- Identify the principal veins that drain the abdomen and pelvis.

The inferior vena cava does not receive veins directly from the gastrointestinal tract, spleen, pancreas, and gallbladder. These organs pass their blood into a common vein, the hepatic portal vein, which delivers the blood to the liver. The superior mesenteric and splenic veins unite to form the hepatic portal vein (see Figure 21.28). This special flow of venous blood, called the hepatic portal circulation, is described shortly. After passing through the liver for processing, blood drains into the hepatic veins, which empty into the inferior vena cava.

<table>
<thead>
<tr>
<th>VEIN</th>
<th>DESCRIPTION AND REGION DRAINED</th>
</tr>
</thead>
<tbody>
<tr>
<td>Inferior vena cava</td>
<td>The two common iliac veins that drain the lower limbs, pelvis, and abdomen unite to form the inferior vena cava. The inferior vena cava extends superiority through the abdomen and thorax to the right atrium.</td>
</tr>
<tr>
<td>Common iliac veins</td>
<td>The common iliac veins are formed by the union of the internal and external iliac veins anterior to the sacroiliac joint and represent the distal continuation of the inferior vena cava at their bifurcation. The right common iliac vein is much shorter than the left and is also more vertical. Generally, the common iliac veins drain the pelvis, external genitalia, and lower limbs.</td>
</tr>
<tr>
<td>Internal iliac veins</td>
<td>The internal iliac veins begin near the superior portion of the greater sciatic notch and run medially to their corresponding arteries. Generally, the veins drain the thigh, buttocks, external genitalia, and pelvis.</td>
</tr>
<tr>
<td>External iliac veins</td>
<td>The external iliac veins are companions of the internal iliac arteries and begin at the inguinal ligaments as continuations of the femoral veins. They end anterior to the sacroiliac joint where they join with the internal iliac veins to form the common iliac veins. The external iliac veins drain the lower limbs, cremaster muscle in males, and the abdominal wall.</td>
</tr>
<tr>
<td>Lumbar veins</td>
<td>A series of parallel lumbar veins, usually four on each side, drain blood from both sides of the posterior abdominal wall, vertebral canal, spinal cord, and meninges. The lumbar veins run horizontally with the lumbar arteries. The lumbar veins connect at right angles with the right and left ascending lumbar veins, which form the origin of the corresponding azygos or hemiazygos vein. The lumbar veins drain blood into the ascending lumbar veins and then run to the inferior vena cava, where they release the remainder of the flow.</td>
</tr>
<tr>
<td>Gonadal veins</td>
<td>The gonadal veins ascend with the gonadal arteries along the posterior abdominal wall. In the male, the gonadal veins are called the testicular veins. The testicular veins drain the testes (the left testicular vein empties into the left renal vein, and the right testicular vein empties into the inferior vena cava). In the female, the gonadal veins are called the ovarian veins. The ovarian veins drain the ovaries. The left ovarian vein empties into the left renal vein, and the right ovarian vein empties into the inferior vena cava.</td>
</tr>
<tr>
<td>Renal veins</td>
<td>The large renal veins pass anterior to the renal arteries. The left renal vein is longer than the right renal vein and passes anterior to the abdominal aorta. It receives the left testicular (or ovarian), left inferior phrenic, and usually left suprarenal veins. The right renal vein empties into the inferior vena cava posterior to the duodenum. The renal veins drain the kidneys.</td>
</tr>
<tr>
<td>Suprarenal veins</td>
<td>The suprarenal veins drain the adrenal (suprarenal) glands (the left suprarenal vein empties into the left renal vein, and the right suprarenal vein empties into the inferior vena cava).</td>
</tr>
<tr>
<td>Inferior phrenic veins</td>
<td>The inferior phrenic veins drain the diaphragm (the left inferior phrenic vein usually sends one tributary to the left suprarenal vein, which empties into the left renal vein, and another tributary that empties into the inferior vena cava; the right inferior phrenic vein empties into the inferior vena cava).</td>
</tr>
<tr>
<td>Hepatic veins</td>
<td>The hepatic veins drain the liver.</td>
</tr>
</tbody>
</table>
CHECKPOINT
What structures do the lumbar, gonadal, renal, suprarenal, inferior phrenic, and hepatic veins drain?
**OBJECTIVE**
- Identify the principal superficial and deep veins that drain the lower limbs.

As with the upper limbs, blood from the lower limbs is drained by both superficial and deep veins. The superficial veins often anastomose with one another and with deep veins along their length. Deep veins, for the most part, have the same names as corresponding arteries (Figure 21.27 on page 817). All veins of the lower limbs have valves, which are more numerous than in veins of the upper limbs.

**CHECKPOINT**
What is the clinical importance of the great saphenous veins?

---

### VEIN
**SUPERFICIAL VEINS**

**Great saphenous veins**
- The great (long) saphenous veins, the longest veins in the body, ascend from the foot to the groin in the subcutaneous layer. They begin at the medial end of the dorsal venous arches of the foot. The dorsal venous arches (VE-nus) are networks of veins on the dorsum of the foot formed by the dorsal digital veins, which collect blood from the toes, and then unite in pairs to form the dorsal metatarsal veins, which parallel the metatarsals. As the dorsal metatarsal veins approach the foot, they combine to form the dorsal venous arches. The great saphenous veins pass anterior to the medial malleolus of the tibia and then superiorly along the medial aspect of the leg and thigh just deep to the skin. They receive tributaries from superficial tissues and connect with the deep veins as well. They empty into the femoral veins at the groin. Generally, the great saphenous veins drain mainly the medial side of the leg and thigh, the groin, external genitals, and abdominal wall. Along their length, the great saphenous veins have from 10 to 20 valves, with more located in the leg than the thigh. These veins are more likely to be subject to varicosities than other veins in the lower limbs because they must support a long column of blood and are not well supported by skeletal muscles.

- The great saphenous veins are often used for prolonged administration of intravenous fluids. This is particularly important in very young children and in patients of any age who are in shock and whose veins are collapsed. In coronary artery bypass grafting, if multiple blood vessels need to be grafted, sections of the great saphenous vein are used along with at least one artery as a graft. After the great saphenous vein is removed and divided into sections, the sections are used to bypass the blockages. The vein grafts are reversed so that the valves do not obstruct the flow of blood.

**Small saphenous veins**
- The small (short) saphenous veins begin at the lateral aspect of the dorsal venous arches of the foot. They pass posterior to the lateral malleolus of the fibula and ascend deep to the skin along the posterior aspect of the leg. They empty into the popliteal veins in the popliteal fossa, posterior to the knee. Along their length, the small saphenous veins have from 9 to 12 valves. The small saphenous veins drain the foot and posterior aspect of the leg. They may communicate with the great saphenous veins in the proximal thigh.

### DEEP VEINS

**Posterior tibial veins**
- The plantar digital veins on the plantar surfaces of the toes unite to form the plantar metatarsal veins, which parallel the metatarsals. They in turn unite to form the deep plantar venous arches. From each arch emerges the medial and lateral plantar veins.

- The medial and lateral plantar veins, posterior to the medial malleolus of the tibia, form the paired posterior tibial veins, which sometimes merge into a single vessel. They accompany the posterior tibial artery through the leg. They ascend deep to the muscles in the posterior aspect of the leg and drain the foot and posterior compartment muscles. About two-thirds of the way up the leg, the posterior tibial veins drain blood from the fibular (peroneal) veins, which drain the lateral and posterior leg muscles. The posterior tibial veins unite with the anterior tibial veins just inferior to the popliteal fossa to form the popliteal veins.

**Anterior tibial veins**
- The paired anterior tibial veins arise in the dorsal venous arch and accompany the anterior tibial artery. They ascend in the interosseous membrane between the tibia and fibula and unite with the posterior tibial veins to form the popliteal vein.

- The anterior tibial veins drain the ankle joint, knee joint, tibiofibular joint, and anterior portion of the leg.

**Popliteal veins**
- The popliteal veins, formed by the union of the anterior and posterior tibial veins, also receive blood from the small saphenous veins and tributaries that correspond to branches of the popliteal artery. The popliteal veins drain the knee joint and the skin, muscles, and bones of portions of the calf and thigh around the knee joint.

**Femoral veins**
- The femoral veins accompany the femoral arteries and are the continuations of the popliteal veins just superior to the knee. The femoral veins extend up the posterior surface of the thighs and drain the muscles of the thighs, femurs, external genitals, and superficial lymph nodes. The largest tributaries of the femoral veins are the deep veins of the thigh (deep femoral veins). Just before penetrating the abdominal wall, the femoral veins receive the deep femoral veins and the great saphenous veins. The veins formed from this union penetrate the body wall and enter the pelvic cavity. Here they are known as the external iliac veins. In order to take blood samples or pressure recordings from the right side of the heart, a catheter is inserted into the femoral vein as it passes through the femoral triangle. The catheter passes through the external and common iliac veins and inferior vena cava into the right atrium.

Which veins of the lower limb are superficial?
The Hepatic Portal Circulation

The hepatic portal circulation carries venous blood from the gastrointestinal organs and spleen to the liver. A vein that carries blood from one capillary network to another is called a portal vein. The hepatic portal vein (hepat- = liver) receives blood from capillaries of gastrointestinal organs and the spleen and delivers it to the sinusoids of the liver (Figure 21.28). After a meal, hepatic portal blood is rich in nutrients absorbed from the gastrointestinal tract. The liver stores some of them and modifies others before they pass into the general circulation. For example, the liver converts glucose into glycogen for storage, reducing blood glucose level shortly after a meal. The liver also detoxifies harmful substances, such as alcohol, that have been absorbed from the gastrointestinal tract and destroys bacteria by phagocytosis.

The superior mesenteric and splenic veins unite to form the hepatic portal vein. The superior mesenteric vein drains blood from the small intestine and portions of the large intestine, stomach, and pancreas through the jejunal, ileal, ileocolic, right colic, middle colic, pancreaticoduodenal, and right gastroepiploic veins. The splenic vein drains blood from the stomach,
pancreas, and portions of the large intestine through the short gastric, left gastroepiploic, pancreatic, and inferior mesenteric veins. The inferior mesenteric vein, which passes into the splenic vein, drains portions of the large intestine through the superior rectal, sigmoidal, and left colic veins. The right and left gastric veins, which open directly into the hepatic portal vein, drain the stomach. The cystic vein, which also opens into the hepatic portal vein, drains the gallbladder.

At the same time the liver is receiving nutrient-rich but deoxygenated blood via the hepatic portal vein, it is also receiving oxygenated blood via the hepatic artery, a branch of the celiac trunk. The oxygenated blood mixes with the deoxygenated blood in sinusoids. Eventually, blood leaves the sinusoids of the liver through the hepatic veins, which drain into the inferior vena cava.

**The Pulmonary Circulation**

The pulmonary circulation (pulmo- = lung) carries deoxygenated blood from the right ventricle to the air sacs (alveoli) within the lungs and returns oxygenated blood from the air sacs to the left atrium (Figure 21.29). The pulmonary trunk emerges from the right ventricle and passes superiorly, posteriorly, and to the left. It then divides into two branches: the right pulmonary artery to the right lung and the left pulmonary artery to the left lung. After birth, the pulmonary arteries are the only arteries that carry deoxygenated blood. On entering the lungs, the branches divide and subdivide until finally they form capillaries around the air sacs (alveoli) within the lungs. CO₂ passes from the blood into the air sacs and is exhaled. Inhaled O₂ passes from the air within the lungs into the blood. The pulmonary capillaries unite to form venules and eventually pulmonary veins, which exit the lungs and carry the oxygenated blood to the left atrium. Two left and two right pulmonary veins enter the left atrium. After birth, the pulmonary veins are the only veins that carry oxygenated blood. Contraction of the left ventricle then ejects the oxygenated blood into the systemic circulation.

**The Fetal Circulation**

The circulatory system of a fetus, called the fetal circulation, exists only in the fetus and contains special structures that allow the developing fetus to exchange materials with its mother (Figure 21.30 on page 821). It differs from the postnatal (after birth) circulation because the lungs, kidneys, and gastrointestinal organs do not begin to function until birth. The fetus obtains O₂ and nutrients from and eliminates CO₂ and other wastes into the maternal blood.

The exchange of materials between fetal and maternal circulations occurs through the placenta (pla-SEN-ta), which forms inside the mother’s uterus and attaches to the umbilicus (navel) of the fetus by the umbilical cord (um-BIL-i-ka). The placenta communicates with the mother’s cardiovascular system through many small blood vessels that emerge from the uterine wall. The umbilical cord contains blood vessels that branch into capillaries in the placenta. Wastes from the fetal blood diffuse out of the capillaries, into spaces containing maternal blood (inter-villous spaces) in the placenta, and finally into the mother’s uterine veins. Nutrients travel the opposite route—from the
maternal blood vessels to the intervillous spaces to the fetal capillaries. Normally, there is no direct mixing of maternal and fetal blood because all exchanges occur by diffusion through capillary walls.

Blood passes from the fetus to the placenta via two umbilical arteries (Figure 21.30a, c). These branches of the internal iliac (hypogastric) arteries are within the umbilical cord. At the placenta, fetal blood picks up O₂ and nutrients and eliminates CO₂ and wastes. The oxygenated blood returns from the placenta via a single umbilical vein. This vein ascends to the liver of the fetus, where it divides into two branches. Some blood flows through the branch that joins the hepatic portal vein and enters the liver, but most of the blood flows into the second branch, the ductus venosus (DUK-tus ve-NO-sus), which drains into the inferior vena cava.

Deoxygenated blood returning from lower body regions of the fetus mingles with oxygenated blood from the ductus venosus in the inferior vena cava. This mixed blood then enters the right atrium. Deoxygenated blood returning from upper body regions of the fetus enters the superior vena cava and also passes into the right atrium.

Most of the fetal blood does not pass from the right ventricle to the lungs, as it does in postnatal circulation, because an opening called the foramen ovale (fo-RÁ-men o-VAL-ë) exists in the septum between the right and left atria. Most of the blood that enters the right atrium passes through the foramen ovale.

Figure 21.29 Pulmonary circulation.

The pulmonary circulation brings deoxygenated blood from the right ventricle to the lungs and returns oxygenated blood from the lungs to the left atrium.

? After birth, which are the only arteries that carry deoxygenated blood?
into the left atrium and joins the systemic circulation. The blood that does pass into the right ventricle is pumped into the pulmonary trunk, but little of this blood reaches the nonfunctioning fetal lungs. Instead, most is sent through the ductus arteriosus (ar-te-ré-O-sus), a vessel that connects the pulmonary trunk with the aorta. The blood in the aorta is carried to all fetal tissues through the systemic circulation. When the common iliac arteries branch into the external and internal iliacs, part of the blood flows into the internal iliacs, into the umbilical arteries, and back to the placenta for another exchange of materials.

**Figure 21.30** Fetal circulation and changes at birth. The gold boxes between parts (a) and (b) describe the fate of certain fetal structures once postnatal circulation is established.

- The lungs and gastrointestinal organs do not begin to function until birth.
After birth, when pulmonary (lung), renal (kidney), and digestive functions begin, the following vascular changes occur (Figure 21.30b):

1. When the umbilical cord is tied off, blood no longer flows through the umbilical arteries, they fill with connective tissue, and the distal portions of the umbilical arteries become fibrous cords called the **medial umbilical ligaments**. Although the arteries are closed functionally only a few minutes after birth, complete obliteration of the lumens may take 2 to 3 months.

2. The umbilical vein collapses but remains as the **ligamentum teres** (round ligament), a structure that attaches the umbilicus to the liver.

3. The ductus venosus collapses but remains as the **ligamentum venosum**, a fibrous cord on the inferior surface of the liver.

4. The placenta is expelled as the “afterbirth.”

5. The foramen ovale normally closes shortly after birth to become the **fossa ovalis**, a depression in the interatrial septum. When an infant takes its first breath, the lungs expand and blood flow to the lungs increases. Blood returning from the lungs to the heart increases pressure in the left atrium. This closes the foramen ovale by pushing the valve that guards it against the interatrial septum. Permanent closure occurs in about a year.

6. The ductus arteriosus closes by vasoconstriction almost immediately after birth and becomes the **ligamentum arteriosum**. Complete anatomical obliteration of the lumen takes 1 to 3 months.

**CHECKPOINT**

23. Diagram the hepatic portal circulation. Why is this route important?
24. Diagram the route of the pulmonary circulation.
25. Discuss the anatomy and physiology of the fetal circulation. Indicate the function of the umbilical arteries, umbilical vein, ductus venosus, foramen ovale, and ductus arteriosus.

**DEVELOPMENT OF BLOOD VESSELS AND BLOOD**

- **OBJECTIVE**

The development of blood cells and the formation of blood vessels begins outside the embryo as early as 15 to 16 days in the **mesoderm** of the wall of the yolk sac, chorion, and connecting...
stalk. About two days later, blood vessels form within the embryo. The early formation of the cardiovascular system is linked to the small amount of yolk in the ovum and yolk sac. As the embryo develops rapidly during the third week, there is a greater need to develop a cardiovascular system to supply sufficient nutrients to the embryo and remove wastes from it.

Blood vessels and blood cells develop from the same precursor cell, called a hemangioblast (hē-MAN-je-ō-blast; hema- = blood; -blast = immature stage). Once mesenchyme develops into hemangioblasts, they can give rise to cells that produce blood vessels (angioblasts) or cells that produce blood cells (pluripotent stem cells).

**Blood vessels** develop from angioblasts, which are derived from hemangioblasts (Figure 21.31). Angioblasts aggregate to form isolated masses and cords throughout the embryonic discs called **blood islands** (Figure 21.31). Spaces soon appear in the islands and become the lumens of the blood vessels. Some of the angioblasts immediately around the spaces give rise to the **endothelial lining of the blood vessels**. Angioblasts around the endothelium form the **tunics** (interna, media, and externa) of the larger blood vessels. Growth and fusion of blood islands form an extensive network of blood vessels throughout the embryo. By continuous branching, blood vessels outside the embryo connect with those inside the embryo, linking the embryo with the placenta.

**Blood cells** develop from **pluripotent stem cells** derived from hemangioblasts. This development occurs in the walls of blood vessels in the yolk sac, chorion, and allantois at about three weeks after fertilization. Blood formation in the embryo itself begins at about the fifth week in the liver and the twelfth week in the spleen, red bone marrow, and thymus.

**CHECKPOINT**

26. What are the sites of blood cell production outside the embryo and within the embryo?

---

**AGING AND THE CARDIOVASCULAR SYSTEM**

**OBJECTIVE**

- Explain the effects of aging on the cardiovascular system.

General changes in the cardiovascular system associated with aging include decreased compliance (distensibility) of the aorta, reduction in cardiac muscle fiber size, progressive loss of cardiac muscular strength, reduced cardiac output, a decline in maximum heart rate, and an increase in systolic blood pressure. Total blood cholesterol tends to increase with age, as does low-density lipoprotein (LDL); high-density lipoprotein (HDL) tends to decrease. There is an increase in the incidence of coronary artery disease (CAD), the major cause of heart disease and death in older Americans. Congestive heart failure, a set of symptoms associated with impaired pumping of the heart, is also prevalent in older individuals. Changes in blood vessels that serve brain tissue—for example, atherosclerosis—reduce nourishment to the brain and result in malfunction or death of brain cells. By age 80, cerebral blood flow is 20% less and renal blood flow is 50% less than in the same person at age 30.

**CHECKPOINT**

27. How does aging affect the heart?

---

To appreciate the many ways the blood, heart, and blood vessels contribute to homeostasis of other body systems, examine Focus on Homeostasis: The Cardiovascular System.

Hypertension

About 50 million Americans have hypertension, or persistently high blood pressure. It is the most common disorder affecting the heart and blood vessels and is the major cause of heart failure, kidney disease, and stroke. In May 2003, the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure published new guidelines for hypertension because clinical studies have linked what were once considered fairly low blood pressure readings to an increased risk of cardiovascular disease. The new guidelines are as follows:

<table>
<thead>
<tr>
<th>Category</th>
<th>Systolic (mmHg)</th>
<th>Diastolic (mmHg)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Normal</td>
<td>Less than 120 and</td>
<td>Less than 80</td>
</tr>
<tr>
<td>Prehypertension</td>
<td>120–139 or</td>
<td>80–89</td>
</tr>
<tr>
<td>Stage 1 hypertension</td>
<td>140–159 or</td>
<td>90–99</td>
</tr>
<tr>
<td>Stage 2 hypertension</td>
<td>Greater than 160 or</td>
<td>Greater than 100</td>
</tr>
</tbody>
</table>

Using the new guidelines, the normal classification was previously considered optimal; prehypertension now includes many more individuals previously classified as normal or high-normal; stage 1 hypertension is the same as in previous guidelines; and stage 2 hypertension now combines the previous stage 2 and stage 3 categories since treatment options are the same for the former stages 2 and 3.

Types and Causes of Hypertension

Between 90 and 95% of all cases of hypertension are primary hypertension, a persistently elevated blood pressure that cannot be attributed to any identifiable cause. The remaining 5–10% of cases are secondary hypertension, which has an identifiable underlying cause. Several disorders cause secondary hypertension:

- **Obstruction of renal blood flow** or disorders that damage renal tissue may cause the kidneys to release excessive amounts of renin into the blood. The resulting high level of angiotensin II causes vasoconstriction, thus increasing systemic vascular resistance.
- **Hypersecretion of aldosterone**—resulting, for instance, from a tumor of the adrenal cortex—stimulates excess reabsorption of salt and water by the kidneys, which increases the volume of body fluids.
- **Hypersecretion of epinephrine and norepinephrine** by a pheochromocytoma (fe-o-kro′-mö-si-TÖ-ma), a tumor of the adrenal medulla. Epinephrine and norepinephrine increase heart rate and contractility and increase systemic vascular resistance.

Damage Effects of Untreated Hypertension

High blood pressure is known as the “silent killer” because it can cause considerable damage to the blood vessels, heart, brain, and kidneys before it causes pain or other noticeable symptoms. It is a major risk factor for the number-one (heart disease) and number-three (stroke) causes of death in the United States. In blood vessels, hypertension causes thickening of the tunica media, accelerates development of atherosclerosis and coronary artery disease, and increases systemic vascular resistance. In the heart, hypertension increases the afterload, which forces the ventricles to work harder to eject blood.

The normal response to an increased workload due to vigorous and regular exercise is hypertrophy of the myocardium, especially in the wall of the left ventricle. An increased afterload, however, leads to myocardial hypertrophy that is accompanied by muscle damage and fibrosis (a buildup of collagen fibers between the muscle fibers). As a result, the left ventricle enlarges, weakens, and dilates. Because arteries in the brain are usually less protected by surrounding tissues than are the major arteries in other parts of the body, prolonged hypertension can eventually cause them to rupture, resulting in a stroke. Hypertension also damages kidney arterioles, causing them to thicken, which narrows the lumen; because the blood supply to the kidneys is thereby reduced, the kidneys secrete more renin, which elevates the blood pressure even more.

Lifestyle Changes to Reduce Hypertension

Although several categories of drugs (described next) can reduce elevated blood pressure, the following lifestyle changes are also effective in managing hypertension:

- **Lose weight.** This is the best treatment for high blood pressure short of using drugs. Loss of even a few pounds helps reduce blood pressure in overweight hypertensive individuals.
- **Limit alcohol intake.** Drinking in moderation may lower the risk of coronary heart disease, mainly among males over 45 and females over 55. Moderation is defined as no more than one 12-oz beer per day for females and no more than two 12-oz beers per day for males.
- **Exercise.** Becoming more physically fit by engaging in moderate activity (such as brisk walking) several times a week for 30 to 45 minutes can lower systolic blood pressure by about 10 mmHg.
- **Reduce intake of sodium (salt).** Roughly half the people with hypertension are “salt sensitive.” For them, a high-salt diet appears to promote hypertension, and a low-salt diet can lower their blood pressure.
- **Maintain recommended dietary intake of potassium, calcium, and magnesium.** Higher levels of potassium, calcium, and magnesium in the diet are associated with a lower risk of hypertension.
- **Don’t smoke.** Smoking has devastating effects on the heart and can augment the damaging effects of high blood pressure by promoting vasoconstriction.
- **Manage stress.** Various meditation and biofeedback techniques help some people reduce high blood pressure. These methods may work by decreasing the daily release of epinephrine and norepinephrine by the adrenal medulla.

Drug Treatment of Hypertension

Drugs having several different mechanisms of action are effective in lowering blood pressure. Many people are successfully treated with diuretics, agents that decrease blood pressure by decreasing blood volume because they increase elimination of water and salt in the urine. ACE (angiotensin converting enzyme) inhibitors block formation of angiotensin II and thereby promote vasodilatation and decrease the secretion of aldosterone. Beta blockers reduce blood pressure by inhibiting the secretion of renin and by decreasing heart rate and contractility. Vasodilators relax the smooth muscle in arterial walls, causing vasodilatation and lowering blood pressure by lowering systemic vascular resistance. An important category of vasodilators are the calcium channel blockers, which slow the inflow of Ca²⁺ into vascular smooth muscle cells. They reduce the heart’s workload by slowing Ca²⁺ entry into pacemaker cells and regular myocardial fibers, thereby decreasing heart rate and the force of myocardial contraction.
MEDICAL TERMINOLOGY

Aneurysm (AN-ū-rizm) A thin, weakened section of the wall of an artery or a vein that bulges outward, forming a balloonlike sac. Common causes are atherosclerosis, syphilis, congenital blood vessel defects, and trauma. If untreated, the aneurysm enlarges and the blood vessel wall becomes so thin that it bursts. The result is massive hemorrhage with shock, severe pain, stroke, or death. Treatment may involve surgery in which the weakened area of the blood vessel is removed and replaced with a graft of synthetic material.

Aortography (ā-ór-TÖG-ra-fē) X-ray examination of the aorta and its main branches after injection of a radiopaque dye.

Carotid endarterectomy (ka-ROT-id end'-ar-ter-EK-tō-mē) The removal of atherosclerotic plaque from the carotid artery to restore greater blood flow to the brain.

Claudication (klaw'-di-KĀ-shun) Pain and lameness or limping caused by defective circulation of the blood in the vessels of the limbs.

Deep vein thrombosis The presence of a thrombus (blood clot) in a deep vein of the lower limbs. It may lead to (1) pulmonary embolism, if the thrombus dislodges and then lodges within the pulmonary arterial blood flow, and (2) postphlebitic syndrome, which consists of edema, pain, and skin changes due to destruction of venous valves.

Doppler ultrasound scanning Imaging technique commonly used to measure blood flow. A transducer is placed on the skin and an image is displayed on a monitor that provides the exact position and severity of a blockage.

Femoral angiography An imaging technique in which a contrast medium is injected into the femoral artery and spreads to other arteries in the lower limb, and then a series of radiographs are taken of one or more sites. It is used to diagnose narrowing or blockage of arteries in the lower limbs.

Hypotension (hī-pō-TEN-shun) Low blood pressure; most commonly used to describe an acute drop in blood pressure, as occurs during excessive blood loss.

Normotensive (nor'-mō-TEN-siv) Characterized by normal blood pressure.

Occlusion (ō-KŁOO-shun) The closure or obstruction of the lumen of a structure such as a blood vessel. An example is an atherosclerotic plaque in an artery.

Orthostatic hypotension (or'-thō-STAT-ik; ortho- = straight; -static = causing to stand) An excessive lowering of systemic blood pressure when a person assumes an erect or semi-erect posture; it is usually a sign of a disease. May be caused by excessive fluid loss, certain drugs, and cardiovascular or neurogenic factors. Also called postural hypotension.

Phlebitis (fle-Bī-tis; phleb- = vein) Inflammation of a vein, often in a leg.

Thrombectomy (throm-BEK-tō-mē; thrombo- = clot) An operation to remove a blood clot from a blood vessel.

Thrombophlebitis (throm'-bō-fle-BI-tis) Inflammation of a vein involving clot formation. Superficial thrombophlebitis occurs in veins under the skin, especially in the calf.

Venipuncture (VEN-i-punk-chur; ven- = vein) The puncture of a vein, usually to withdraw blood for analysis or introduce a solution, for example, an antibiotic. The median cubital vein is frequently used.

White coat (office) hypertension A stress-induced syndrome found in patients who have elevated blood pressure when being examined by health-care personnel, but otherwise have normal blood pressure.

STUDY OUTLINE

Structure and Function of Blood Vessels (p. 761)

1. Arteries carry blood away from the heart. The wall of an artery consists of a tunica interna, a tunica media (which maintains elasticity and contractility), and a tunica externa.
2. Large arteries are termed elastic (conducting) arteries, and medium-sized arteries are called muscular (distributing) arteries.
3. Many arteries anastomose: The distal ends of two or more vessels unite. An alternative blood route from an anastomosis is called collateral circulation. Arteries that do not anastomose are called end arteries.
4. Arterioles are small arteries that deliver blood to capillaries.
5. Through constriction and dilation, arterioles assume a key role in regulating blood flow from arteries into capillaries and in altering arterial blood pressure.
6. Capillaries are microscopic blood vessels through which materials are exchanged between blood and tissue cells; some capillaries are continuous, and others are fenestrated.
7. Capillaries branch to form an extensive network throughout a tissue. This network increases surface area, allowing a rapid exchange of large quantities of materials.
8. Precapillary sphincters regulate blood flow through capillaries.
9. Microscopic blood vessels in the liver are called sinusoids.
10. Venules are small vessels that continue from capillaries and merge to form veins.
11. Veins consist of the same three tunics as arteries but have a thinner tunica interna and a thinner tunica media. The lumen of a vein is also larger than that of a comparable artery.
12. Veins contain valves to prevent backflow of blood.
13. Weak valves can lead to varicose veins.
14. Vascular (venous) sinuses are veins with very thin walls.
15. Systemic veins are collectively called blood reservoirs because they hold a large volume of blood. If the need arises, this blood can be shifted into other blood vessels through vasoconstriction of veins.
16. The principal blood reservoirs are the veins of the abdominal organs (liver and spleen) and skin.

Capillary Exchange (p. 769)

1. Substances enter and leave capillaries by diffusion, transcytosis, or bulk flow.
2. The movement of water and solutes (except proteins) through capillary walls depends on hydrostatic and osmotic pressures.
3. The near equilibrium between filtration and reabsorption in capillaries is called Starling’s law of the capillaries.
4. Edema is an abnormal increase in interstitial fluid.
Hemodynamics: Factors Affecting Blood Flow (p. 772)

1. The velocity of blood flow is inversely related to the cross-sectional area of blood vessels; blood flows slowest where cross-sectional area is greatest.
2. The velocity of blood flow decreases from the aorta to arteries to capillaries and increases in venules and veins.
4. Blood flows from regions of higher to lower pressure. The higher the resistance, however, the lower the blood flow.
5. Cardiac output equals the mean arterial pressure divided by total resistance \( \text{CO} = \frac{\text{MAP}}{R} \).
6. Blood pressure is the pressure exerted on the walls of a blood vessel.
7. Factors that affect blood pressure are cardiac output, blood volume, viscosity, resistance, and the elasticity of arteries.
8. As blood leaves the aorta and flows through the systemic circulation, its pressure progressively falls to 0 mmHg by the time it reaches the right ventricle.
9. Resistance depends on blood vessel diameter, blood viscosity, and total blood vessel length.
10. Venous return depends on pressure differences between the venules and the right ventricle.
11. Blood return to the heart is maintained by several factors, including skeletal muscular contractions, valves in veins (especially in the limbs), and pressure changes associated with breathing.

Control of Blood Pressure and Blood Flow (p. 775)

1. The cardiovascular (CV) center is a group of neurons in the medulla oblongata that regulates heart rate, contractility, and blood vessel diameter.
2. The cardiovascular center receives input from higher brain regions and sensory receptors (baroreceptors and chemoreceptors).
3. Output from the cardiovascular center flows along sympathetic and parasympathetic axons. Sympathetic impulses propagated along cardioaccelerator nerves increase heart rate and contractility; parasympathetic impulses propagated along vagus nerves decrease heart rate.
4. Baroreceptors monitor blood pressure, and chemoreceptors monitor blood levels of \( \text{O}_2 \), \( \text{CO}_2 \), and hydrogen ions. The carotid sinus reflex helps regulate blood pressure in the brain. The aortic reflex regulates general systemic blood pressure.
5. Hormones that help regulate blood pressure are epinephrine, norepinephrine, ADH (vasopressin), angiotensin II, and ANP.
6. Autoregulation refers to local, automatic adjustments of blood flow in a given region to meet a particular tissue's need.
7. \( \text{O}_2 \) level is the principal stimulus for autoregulation.

Checking Circulation (p. 780)

1. Pulse is the alternate expansion and elastic recoil of an artery wall with each heartbeat. It may be felt in any artery that lies near the surface or over a hard tissue.
2. A normal resting pulse (heart) rate is 70–80 beats/min.
3. Blood pressure is the pressure exerted by blood on the wall of an artery when the left ventricle undergoes systole and then diastole. It is measured by the use of a sphygmomanometer.
4. Systolic blood pressure (SBP) is the arterial blood pressure during ventricular contraction. Diastolic blood pressure (DBP) is the arterial blood pressure during ventricular relaxation. Normal blood pressure is less than 120/80.
5. Pulse pressure is the difference between systolic and diastolic blood pressure. It normally is about 40 mmHg.

Shock and Homeostasis (p. 781)

1. Shock is a failure of the cardiovascular system to deliver enough \( \text{O}_2 \) and nutrients to meet the metabolic needs of cells.
2. Types of shock include hypovolemic, cardiogenic, vascular, and obstructive.
3. Signs and symptoms of shock include systolic blood pressure less than 90 mmHg; rapid resting heart rate; weak, rapid pulse; clammy, cool, pale skin; sweating; hypotension; altered mental state; decreased urinary output; thirst; and acidosis.

Circulatory Routes (p. 783)

1. The two main circulatory routes are the systemic and pulmonary circulations.
2. Among the subdivisions of the systemic circulation are the coronary (cardiac) circulation and the hepatic portal circulation.
3. The systemic circulation carries oxygenated blood from the left ventricle through the aorta to all parts of the body, including some lung tissue, but not the air sacs (alveoli) of the lungs, and returns the deoxygenated blood to the right atrium.
4. The aorta is divided into the ascending aorta, the arch of the aorta, and the descending aorta. Each section gives off arteries that branch to supply the whole body.
5. Blood returns to the heart through the systemic veins. All veins of the systemic circulation drain into the superior or inferior vena cavae or the coronary sinus, which in turn empty into the right atrium.
6. The major blood vessels of the systemic circulation may be reviewed in Exhibits 21.1–21.12 on pages 785–817.
7. The hepatic portal circulation directs venous blood from the gastrointestinal organs and spleen into the hepatic portal vein of the liver before it returns to the heart. It enables the liver to utilize nutrients and detoxify harmful substances in the blood.
8. The pulmonary circulation takes deoxygenated blood from the right ventricle to the alveoli within the lungs and returns oxygenated blood from the alveoli to the left atrium.
9. Fetal circulation exists only in the fetus. It involves the exchange of materials between fetus and mother via the placenta.
10. The fetus derives \( \text{O}_2 \) and nutrients from and eliminates \( \text{CO}_2 \) and wastes into maternal blood. At birth, when pulmonary (lung), digestive, and liver functions begin, the special structures of fetal circulation are no longer needed.

Development of Blood Vessels and Blood (p. 822)

1. Blood vessels develop from mesenchyme (hemangioblasts → angioblasts → blood islands) in mesoderm called blood islands.
2. Blood cells also develop from mesenchyme (hemangioblasts → pluripotent stem cells).
3. The development of blood cells from pluripotent stem cells derived from angioblasts occurs in the walls of blood vessels in the yolk sac, chorion, and allantois at about three weeks after fertilization. Within the embryo, blood is produced by the liver at about the fifth week and in the spleen, red bone marrow, and thymus at about the twelfth week.
Aging and the Cardiovascular System (p. 823)

1. General changes associated with aging include reduced compliance (distensibility) of blood vessels, reduction in cardiac muscle size, reduced cardiac output, and increased systolic blood pressure.

2. The incidence of coronary artery disease (CAD), congestive heart failure (CHF), and atherosclerosis increases with age.

**SELF-QUIZ QUESTIONS**

Fill in the blanks in the following statements.

1. The _____ reflex helps maintain normal blood pressure in the brain; the _____ reflex governs general systemic blood pressure.

2. In addition to the pressure created by contraction of the left ventricle, venous return is aided by the _____ and the _____, both of which depend on the presence of valves in the veins.

Indicate whether the following statements are true or false.

3. Baroreceptors and chemoreceptors are located in the aorta and carotid arteries.

4. The most important method of capillary exchange is simple diffusion.

Choose the one best answer to the following questions.

5. Which of the following are not true? (1) Muscular arteries are also known as conducting arteries. (2) Capillaries play a key role in regulating resistance. (3) The flow of blood through true capillaries is controlled by precapillary sphincters. (4) The lumen of an artery is larger than in a comparable vein. (5) Elastic arteries help propel blood. (6) The tunica media of arteries is thicker than the tunica media of veins.

(a) 2, 3, and 6 (b) 1, 2, and 4 (c) 1, 2, 4, and 6 (d) 3, 4, and 5 (e) 1, 2, 3, and 4

6. Which of the following are true concerning capillary exchange? (1) Large, lipid-insoluble molecules cross capillary walls by transcytosis. (2) The blood hydrostatic pressure promotes reabsorption of fluid into the capillaries. (3) If the pressures that promote filtration are greater than the pressures that promote reabsorption, fluid will move out of a capillary and into interstitial spaces. (4) A negative net filtration pressure results in reabsorption of fluid from interstitial spaces into a capillary. (5) The difference in osmotic pressure across a capillary wall is due primarily to red blood cells.

(a) 1, 3, and 4 (b) 1, 2, 3, 4, and 5 (c) 1, 2, 3, and 4 (d) 3 and 4 (e) 2, 4, and 5

7. Which of the following would not increase vascular resistance? (1) vasodilation, (2) polycythemia, (3) obesity, (4) dehydration, (5) anemia.

(a) 1 and 2 (b) 1, 3, and 4 (c) 1 and 5 (d) 1, 4, and 5 (e) 1 only

8. Capillary exchange is enhanced by (1) the slow rate of flow through the capillaries, (2) a small cross-sectional area, (3) the thinness of capillary walls, (4) the respiratory pump, (5) extensive branching, which increases the surface area.

(a) 1, 2, 3, 4, and 5 (b) 1, 2, 3, and 5 (c) 1 and 3 (d) 3 and 5 (e) 1, 3, and 5

9. Systemic vascular resistance depends on which of the following factors? (1) blood viscosity, (2) total blood vessel length, (3) size

10. Which of the following help regulate blood pressure and help control regional blood flow? (1) baroreceptor and chemoreceptor reflexes, (2) hormones, (3) autoregulation, (4) H⁺ concentration of blood, (5) oxygen concentration of the blood.

(a) 1, 2, and 4 (b) 2, 4, and 5 (c) 1, 4, and 5 (d) 1, 2, 3, 4, and 5 (e) 3, 4, and 5

11. For each of the following, indicate if it causes vasoconstriction or vasodilation. Use D for vasodilation and C for vasoconstriction.

(a) atrial natriuretic peptide (b) ADH (c) decrease in body temperature (d) lactic acid (e) histamine (f) hypoxia (g) hypercapnia (h) angiotensin II (i) nitric oxide (j) decreased sympathetic (k) acidosis impulses

12. Match the following:

- pressure generated by the pumping of the heart; pushes fluids out of capillaries
- pressure created by proteins present in the interstitial fluid; pulls fluid out of capillaries
- balance of pressure; determines whether blood volume and interstitial fluid remain steady or change
- force due to presence of plasma proteins; pulls fluid into capillaries from interstitial spaces
- pressure due to fluid in interstitial spaces; pushes fluid back into capillaries

(a) net filtration pressure (b) blood hydrostatic pressure (c) interstitial fluid hydrostatic pressure (d) blood colloid osmotic pressure (e) interstitial fluid osmotic pressure
13. Match the following:
   (a) supplies blood to the kidney
   (b) drains blood from the small intestine, portions of the large intestine, stomach, and pancreas
   (c) main blood supply to arm; commonly used to measure blood pressure
   (d) supply blood to the free lower limbs
   (e) drain oxygenated blood from the lungs and send it to the left atrium
   (f) supplies blood to the stomach, liver, and pancreas
   (g) supply blood to the brain
   (h) supplies blood to the large intestine
   (i) drain blood from the head
   (j) detours venous blood from the gastrointestinal organs and spleen through the liver before it returns to the heart
   (k) drains most of the thorax and abdominal wall; can serve as a bypass for the inferior vena cava
   (l) a part of the venous circulation of the leg; a vessel used in heart bypass surgery
   (m) carry deoxygenated blood from the right ventricle to the lungs

14. Match the following:
   (a) a traveling pressure wave created by the alternate expansion and recoil of elastic arteries after each systole of the left ventricle
   (b) the lowest blood pressure in arteries during ventricular relaxation
   (c) a slow resting heart rate or pulse rate
   (d) an inadequate cardiac output that results in a failure of the cardiovascular system to deliver enough oxygen and nutrients to meet the metabolic needs of body cells
   (e) a rapid resting heart rate or pulse rate
   (f) the highest force with which blood pushes against arterial walls as a result of ventricular contraction

15. Match the following (some answers will be used more than once):
   (a) returns oxygenated blood from the placenta to the fetal liver
   (b) an opening in the septum between the right and left atria
   (c) becomes the ligamentum venosum after birth
   (d) passes blood from the fetus to the placenta
   (e) bypasses the nonfunctioning lungs; becomes the ligamentum arteriosum at birth
   (f) become the medial umbilical ligaments at birth
   (g) transports oxygenated blood into the inferior vena cava
   (h) becomes the ligamentum teres at birth
   (i) becomes the fossa ovalis after birth

CRITICAL THINKING QUESTIONS

1. Kim Sung was told that her baby was born with a hole in the upper chambers of his heart. Is this something Kim Sung should worry about?

2. Michael was brought into the emergency room suffering from a gunshot wound. He is bleeding profusely and exhibits the following: systolic blood pressure is 40 mmHg; weak pulse of 200 beats per minute; cool, pale, and clammy skin. Michael is not producing urine but is asking for water. He is confused and disoriented. What is his diagnosis and what, specifically, is causing these symptoms?

3. Maureen’s job entails standing on a concrete floor for 10-hour days on an assembly line. Lately she has noticed swelling in her ankles at the end of the day and some tenderness in her calves. What do you suspect is Maureen’s problem and how could she help counteract the problem?
21.1 The femoral artery has the thicker wall; the femoral vein has the wider lumen.

21.2 Due to atherosclerosis, less energy is stored in the less-compliant elastic arteries during systole; thus, the heart must pump harder to maintain the same rate of blood flow.

21.3 Metabolically active tissues use O₂ and produce wastes more rapidly than inactive tissues, so they require more extensive capillary networks.

21.4 Materials cross capillary walls through intercellular clefts and fenestrations, via transcytosis in pinocytic vesicles, and through the plasma membranes of endothelial cells.

21.5 Valves are more important in arm veins and leg veins than in neck veins because, when you are standing, gravity causes pooling of blood in the veins of the free limbs but aids the flow of blood in neck veins back toward the heart.

21.6 Blood volume in veins is about 64% of 5 liters, or 3.2 liters; blood volume in capillaries is about 7% of 5 liters, or 350 mL.

21.7 Blood colloid osmotic pressure is lower than normal in a person with a low level of plasma proteins, and therefore capillary reabsorption is low. The result is edema.

21.8 Mean blood pressure in the aorta is closer to diastolic than to systolic pressure.

21.9 The skeletal muscle pump and respiratory pump aid venous return.

21.10 Vasodilation and vasoconstriction of arterioles are the main regulators of systemic vascular resistance.

21.11 Velocity of blood flow is fastest in the aorta and arteries.

21.12 The effector tissues regulated by the cardiovascular center are cardiac muscle in the heart and smooth muscle in blood vessel walls.

21.13 Impulses to the cardiovascular center pass from baroreceptors in the carotid sinuses via the glossopharyngeal (IX) nerves and from baroreceptors in the arch of the aorta via the vagus (X) nerves.

21.14 It represents a change that occurs when you stand up because gravity causes pooling of blood in leg veins once you are upright, decreasing the blood pressure in your upper body.

Diastolic blood pressure = 95 mmHg; systolic blood pressure = 142 mmHg; pulse pressure = 47 mmHg. This person has stage I hypertension because the systolic blood pressure is greater than 140 mmHg and the diastolic blood pressure is greater than 90 mmHg.

21.16 Almost-normal blood pressure in a person who has lost blood does not necessarily indicate that the patient’s tissues are receiving adequate blood flow; if systemic vascular resistance has increased greatly, tissue perfusion may be inadequate.

21.17 The two main circulatory routes are the systemic circulation and the pulmonary circulation.

21.18 The subdivisions of the aorta are the ascending aorta, arch of the aorta, thoracic aorta, and abdominal aorta.

21.19 Branches of the arch of aorta (in order of origination) are the brachiocephalic trunk, left common carotid artery, and left subclavian artery.

21.20 The thoracic aorta begins at the level of the intervertebral disc between T4 and T5.

21.21 The abdominal aorta begins at the aortic hiatus in the diaphragm.

21.22 The abdominal aorta divides into the common iliac arteries at about the level of L4.

21.23 The superior vena cava drains regions above the diaphragm, and the inferior vena cava drains regions below the diaphragm.

21.24 All venous blood in the brain drains into the internal jugular veins.

21.25 The median cubital vein of the free upper limb is often used for withdrawing blood.

21.26 The inferior vena cava returns blood from abdominopelvic viscera to the heart.

21.27 Superficial veins of the free lower limbs are the dorsal venous arch and the great saphenous and small saphenous veins.

21.28 The hepatic veins carry blood away from the liver.

21.29 After birth, the pulmonary arteries are the only arteries that carry deoxygenated blood.

21.30 Exchange of materials between mother and fetus occurs across the placenta.

21.31 Blood vessels and blood are derived from mesoderm.
THE LYMPHATIC SYSTEM, DISEASE RESISTANCE, AND HOMEOSTASIS

The lymphatic system contributes to homeostasis by draining interstitial fluid as well as providing the mechanisms for defense against disease.

Maintaining homeostasis in the body requires continual combat against harmful agents in our internal and external environment. Despite constant exposure to a variety of pathogens (PATH-øjenz), disease-producing microbes such as bacteria and viruses, most people remain healthy. The body surface also endures cuts and bumps, exposure to ultraviolet rays in sunlight, chemical toxins, and minor burns with an array of defensive ploys.

Immunity or resistance is the ability to ward off damage or disease through our defenses. Vulnerability or lack of resistance is termed susceptibility. The two general types of immunity are (1) innate and (2) adaptive. Innate (nonspecific) immunity refers to defenses that are present at birth. They are always present and available to provide rapid responses to protect us against disease. Innate immunity does not involve specific recognition of a microbe and acts against all microbes in the same way. In addition, innate immunity does not have a memory component; that is, it cannot recall a previous contact with a foreign molecule. Among the components of innate immunity are the first line of defense (the physical and chemical barriers of the skin and mucous membranes) and the second line of defense (antimicrobial substances, natural killer cells, phagocytes, inflammation, and fever). Innate immune responses represent immunity’s early warning system and are designed to prevent microbes from gaining access into the body and to help eliminate those that do gain access.

Adaptive (specific) immunity refers to defenses that involve specific recognition of a microbe once it has breached the innate immunity defenses. Adaptive immunity is based on a specific response to a specific microbe; that is, it adapts or adjusts to handle a specific microbe. Unlike innate immunity, adaptive immunity is slower to respond, but it does have a memory component. Adaptive immunity involves lymphocytes (a type of white blood cell) called T lymphocytes (T cells) and B lymphocytes (B cells).

The body system responsible for adaptive immunity (and some aspects of innate immunity) is the lymphatic system. This system is closely allied with the cardiovascular system, and it also functions with the digestive system in the absorption of fatty foods. In this chapter, we will explore the mechanisms that provide defenses against intruders and promote the repair of damaged body tissues.
LYMPHATIC SYSTEM STRUCTURE AND FUNCTION

**OBJECTIVES**
- List the components and major functions of the lymphatic system.
- Describe the organization of lymphatic vessels.
- Explain the formation and flow of lymph.
- Compare the structure and functions of the primary and secondary lymphatic organs and tissues.

The lymphatic system (lim-FAT-ik) consists of a fluid called lymph, vessels called lymphatic vessels that transport the lymph, a number of structures and organs containing lymphatic tissue, and red bone marrow, where stem cells develop into the various types of blood cells, including lymphocytes (Figure 22.1). It assists in circulating body fluids and helps defend the body against disease-causing agents. As you will see shortly, most components of blood plasma filter through blood capillary walls to form interstitial fluid. After interstitial fluid passes into lymphatic vessels, it is called lymph (LIMF = clear fluid). The major difference between interstitial fluid and lymph is location: Interstitial fluid is found between cells, and lymph is located within lymphatic vessels and lymphatic tissue.

**Lymphatic tissue** is a specialized form of reticulon connective tissue (see Table 4.4C on page 129) that contains large numbers of lymphocytes. Recall from Chapter 19 that lymphocytes are agranular white blood cells (see page 699). Two types of lymphocytes participate in adaptive immune responses: B cells and T cells.

**Functions of the Lymphatic System**
The lymphatic system has three primary functions:

1. **Drains excess interstitial fluid.** Lymphatic vessels drain excess interstitial fluid from tissue spaces and return it to the blood.
2. **Transports dietary lipids.** Lymphatic vessels transport lipids and lipid-soluble vitamins (A, D, E, and K) absorbed by the gastrointestinal tract.
3. **Carries out immune responses.** Lymphatic tissue initiates highly specific responses directed against particular microbes or abnormal cells.

**Lymphatic Vessels and Lymph Circulation**
Lymphatic vessels begin as lymphatic capillaries. These tiny vessels, which are located in the spaces between cells, are closed at one end (Figure 22.2 on page 834). Just as blood capillaries converge to form venules and then veins, lymphatic capillaries unite to form larger lymphatic vessels (see Figure 22.1), which resemble veins in structure but have thinner walls and more valves. At intervals along the lymphatic vessels, lymph flows through lymph nodes, encapsulated bean-shaped organs consisting of masses of B cells and T cells. In the skin, lymphatic vessels lie in the subcutaneous tissue and generally follow the same route as veins; lymphatic vessels of the viscera generally follow arteries, forming plexuses (networks) around them. Tissues that lack lymphatic capillaries include avascular tissues (such as cartilage, the epidermis, and the cornea of the eye), the central nervous system, portions of the spleen, and red bone marrow.

**Lymphatic Capillaries**
Lymphatic capillaries are slightly larger in diameter than blood capillaries and have a unique one-way structure that permits interstitial fluid to flow into them but not out. The ends of endothelial cells that make up the wall of a lymphatic capillary overlap (Figure 22.2b). When pressure is greater in the interstitial fluid than in lymph, the cells separate slightly, like the opening of a one-way swinging door, and interstitial fluid enters the lymphatic capillary. When pressure is greater inside the lymphatic capillary, the cells adhere more closely, and lymph cannot escape back into interstitial fluid. The pressure is relieved as lymph moves further down the lymphatic capillary. Attached to the lymphatic capillaries are anchoring filaments, which contain elastic fibers. They extend out from the lymphatic capillary, attaching lymphatic endothelial cells to surrounding tissues. When excess interstitial fluid accumulates and causes tissue swelling, the anchoring filaments are pulled, making the openings between cells even larger so that more fluid can flow into the lymphatic capillary.

In the small intestine, specialized lymphatic capillaries called lacteals (LAK-té-als; lact- = milky) carry dietary lipids into lymphatic vessels and ultimately into the blood. The presence of these lipids causes the lymph draining from the small intestine to appear creamy white; such lymph is referred to as chyle (KIŁ = juice). Elsewhere, lymph is a clear, pale-yellow fluid.

**Lymph Trunks and Ducts**
As you have already learned, lymph passes from lymphatic capillaries into lymphatic vessels and then through lymph nodes. As lymphatic vessels exit lymph nodes in a particular region of the body, they unite to form lymph trunks. The principal trunks are the lumbar, intestinal, bronchomediastinal, subclavian, and jugular trunks (Figure 22.3 on page 835). The lumbar trunks drain lymph from the lower limbs, the wall and viscera of the pelvis, the kidneys, the adrenal glands, and the abdominal wall. The intestinal trunk drains lymph from the stomach, intestines, pancreas, spleen, and part of the liver. The bronchomediastinal trunks drain lymph from the thoracic wall, lung, and heart. The subclavian trunks drain the upper limbs. The jugular trunks drain the head and neck.

Lymph passes from lymph trunks into two main channels, the thoracic duct and the right lymphatic duct, and then drains into venous blood. The thoracic (left lymphatic) duct is about 38–45 cm (15–18 in.) long and begins as a dilation called the cisterna chyli (sis-TER-na KI-lé; cisterna = cavity or reservoir) anterior to the second lumbar vertebra. The thoracic duct is the main duct for the return of lymph to blood. The cisterna
Figure 22.1 Components of the lymphatic system.

The lymphatic system consists of lymph, lymphatic vessels, lymphatic tissues, and red bone marrow.

Functions

1. Drains excess interstitial fluid.
2. Transports dietary lipids from the gastrointestinal tract to the blood.
3. Protects against invasion through immune responses.

What tissue contains stem cells that develop into lymphocytes?
chyli receives lymph from the right and left lumbar trunks and from the intestinal trunk. In the neck, the thoracic duct also receives lymph from the left jugular, left subclavian, and left bronchomediastinal trunks. Therefore, the thoracic duct receives lymph from the left side of the head, neck, and chest, the left upper limb, and the entire body inferior to the ribs (see Figure 22.1b). The thoracic duct in turn drains lymph into venous blood at the junction of the left internal jugular and left subclavian veins.

The right lymphatic duct (Figure 22.3) is about 1.2 cm (0.5 in.) long and receives lymph from the right jugular, right subclavian, and right bronchomediastinal trunks. Thus, the right lymphatic duct receives lymph from the upper right side of the body (see Figure 22.1b). From the right lymphatic duct, lymph drains into venous blood at the junction of the right internal jugular and right subclavian veins.

**Formation and Flow of Lymph**

Most components of blood plasma filter freely through the capillary walls to form interstitial fluid, but more fluid filters out of blood capillaries than returns to them by reabsorption (see Figure 21.7 on page 771). The excess filtered fluid—about 3 liters per day—drains into lymphatic vessels and becomes lymph. Because most plasma proteins are too large to leave blood vessels, interstitial fluid contains only a small amount of protein. Proteins that do leave blood plasma cannot return to the blood by diffusion because the concentration gradient (high level of proteins inside blood capillaries, low level outside) opposes such movement. The proteins can, however, move readily through the more permeable lymphatic capillaries into lymph. Thus, an important function of lymphatic vessels is to return the lost plasma proteins to the bloodstream.

Like veins, lymphatic vessels contain valves, which ensure the one-way movement of lymph. As noted previously, lymph drains into venous blood through the right lymphatic duct and the thoracic duct at the junction of the internal jugular and subclavian veins (Figure 22.3). Thus, the sequence of fluid flow is blood capillaries (blood) → interstitial spaces (interstitial fluid) → lymphatic capillaries (lymph) → lymphatic vessels (lymph) → lymphatic ducts (lymph) → junction of the internal jugular and subclavian veins (blood). Figure 22.4 on page 837 illustrates this sequence, along with the relationship of the lymphatic and cardiovascular systems.

The same two "pumps" that aid the return of venous blood to the heart maintain the flow of lymph.

1. **Skeletal muscle pump.** The “milking action” of skeletal muscle contractions (see Figure 21.9 on page 774) compresses lymphatic vessels (as well as veins) and forces lymph toward the junction of the internal jugular and subclavian veins.

2. **Respiratory pump.** Lymph flow is also maintained by pressure changes that occur during inhalation (breathing in). Lymph flows from the abdominal region, where the pressure is higher, toward the thoracic region, where it is lower. When the pressures reverse during exhalation (breathing out), the valves prevent backflow of lymph. In addition, when a lymphatic vessel...
Figure 22.3 Routes for drainage of lymph from lymph trunks into the thoracic and right lymphatic ducts.

All lymph returns to the bloodstream through the thoracic (left) lymphatic duct and right lymphatic duct.

Which lymphatic vessels empty into the cisterna chyli, and which duct receives lymph from the cisterna chyli?
distends, the smooth muscle in its wall contracts, which helps move lymph from one segment of the vessel to the next.

**Lymphatic Organs and Tissues**

The widely distributed lymphatic organs and tissues are classified into two groups based on their functions. **Primary lymphatic organs** are the sites where stem cells divide and become immunocompetent, that is, capable of mounting an immune response. The primary lymphatic organs are the red bone marrow (in flat bones and the epiphyses of long bones of adults) and the thymus. Pluripotent stem cells in red bone marrow give rise to mature, immunocompetent B cells and to pre-T cells. The pre-T cells in turn migrate to the thymus, where they become immunocompetent T cells. The **secondary lymphatic organs and tissues** are the sites where most immune responses occur. They include lymph nodes, the spleen, and lymphatic nodules (follicles). The thymus, lymph nodes, and spleen are considered organs because each is surrounded by a connective tissue capsule; lymphatic nodules, in contrast, are not considered organs because they lack a capsule.

**Thymus**

The **thymus** is a bilobed organ located in the mediastinum between the sternum and the aorta (Figure 22.5a). An enveloping layer of connective tissue holds the two lobes closely together, but a connective tissue capsule separates the two. Extensions of the capsule, called **trabeculae** (tra-BEK-û-lé = little beams), penetrate inward and divide each lobe into **lobules** (Figure 22.5b).

Each thymic lobule consists of a deeply staining outer cortex and a lighter-staining central medulla (Figure 22.5b). The **cortex** is composed of large numbers of T cells and scattered dendritic cells, epithelial cells, and macrophages. Immature T cells (pre-T cells) migrate from red bone marrow to the cortex of the thymus, where they proliferate and begin to mature. **Dendritic cells** (dendr = a tree), which are derived from monocytes, and so named because they have long, branched projections that resemble the dendrites of a neuron, assist the maturation process. As you will see shortly, dendritic cells in other parts of the body, such as lymph nodes, play another key role in immune responses. Each of the specialized **epithelial cells** in the cortex has several long processes that surround and serve as a framework.
for as many as 50 T cells. These epithelial cells help “educate” the pre-T cells in a process known as positive selection (see Figure 22.22). Additionally, they produce thymic hormones that are thought to aid in the maturation of T cells. Only about 2% of developing T cells survive in the cortex. The remaining cells die via apoptosis (programmed cell death). Thymic macrophages help clear out the debris of dead and dying cells. The surviving T cells enter the medulla.

The medulla consists of widely scattered, more mature T cells, epithelial cells, dendritic cells, and macrophages (Figure 22.5c). Some of the epithelial cells become arranged into concentric layers of flat cells that degenerate and become filled with keratohyalin granules and keratin. These clusters are called thymic (Hassall’s) corpuscles. Although their role is uncertain, they may serve as sites of T cell death in the medulla. T cells that leave the thymus via the blood migrate to lymph nodes, the spleen, and other lymphatic tissues where they colonize parts of these organs and tissues.

In infants, the thymus is large, with a mass of about 70 g (2.3 oz). After puberty, adipose and areolar connective tissue begin to replace the thymic tissue. By the time a person reaches maturity, the gland has atrophied considerably, and in old age it may weigh only 3 g (0.1 oz). Before the thymus atrophies, it populates the secondary lymphatic organs and tissues with T cells. However, some T cells continue to proliferate in the thymus throughout an individual’s lifetime.

Lymph Nodes

Located along lymphatic vessels are about 600 bean-shaped lymph nodes. They are scattered throughout the body, both superficially and deep, and usually occur in groups (see Figure 22.1). Large groups of lymph nodes are present near the mammary glands and in the axillae and groin.

Lymph nodes are 1–25 mm (0.04–1 in.) long and, like the thymus, are covered by a capsule of dense connective tissue that extends into the node (Figure 22.6). The capsular extensions,
Figure 22.6 Structure of a lymph node. Arrows indicate the direction of lymph flow through a lymph node. Lymph nodes are present throughout the body, usually clustered in groups.
called trabeculae, divide the node into compartments, provide support, and provide a route for blood vessels into the interior of a node. Internal to the capsule is a supporting network of reticular fibers and fibroblasts. The capsule, trabeculae, reticular fibers, and fibroblasts constitute the stroma (supporting connective tissue) of a lymph node.

The parenchyma (functioning part) of a lymph node is divided into a superficial cortex and a deep medulla. The cortex consists of an outer cortex and an inner cortex. Within the outer cortex are egg-shaped aggregates of B cells called lymphatic nodules (follicles). A lymphatic nodule consisting chiefly of B cells is called a primary lymphatic nodule. Most lymphatic nodules in the outer cortex are secondary lymphatic nodules (Figure 22.6), which form in response to an antigenic challenge and are sites of plasma cell and memory B cell formation. After B cells in a primary lymphatic nodule recognize an antigen, the primary lymphatic nodule develops into a secondary lymphatic nodule. The center of a secondary lymphatic nodule contains a region of light-staining cells called a germinal center. In the germinal center are B cells, follicular dendritic cells (a special type of dendritic cell), and macrophages. When follicular dendritic cells “present” an antigen (described later in the chapter), B cells proliferate and develop into antibody-producing plasma cells or develop into memory B cells. Memory B cells persist after an initial immune response and “remember” having encountered a specific antigen. B cells that do not develop properly undergo apoptosis (programmed cell death) and are destroyed by macrophages. The region of a secondary lymphatic nodule surrounding the germinal center is composed of dense accumulations of B cells that have migrated away from their site of origin within the nodule.

The inner cortex does not contain lymphatic nodules. It consists mainly of T cells and dendritic cells that enter a lymph node from other tissues. The dendritic cells present antigens to T cells, causing their proliferation. The newly formed T cells then migrate from the lymph node to areas of the body where there is antigenic activity.

The medulla of a lymph node contains B cells, antibody producing plasma cells that have migrated out of the cortex into the medulla, and macrophages. The various cells are embedded in a network of reticular fibers and reticular cells.

As you have already learned, lymph flows through a node in one direction only (Figure 22.6a). It enters through afferent lymphatic vessels (afferent = to carry toward), which penetrate the convex surface of the node at several points. The afferent vessels contain valves that open toward the center of the node, directing the lymph inward. Within the node, lymph enters sinuses, a series of irregular channels that contain branching reticular fibers, lymphocytes, and macrophages. From the afferent lymphatic vessels, lymph flows into the subcapsular sinus, immediately beneath the capsule. From here the lymph flows through trabecular sinuses, which extend through the cortex parallel to the trabeculae, and into medullary sinuses, which extend through the medulla. The medullary sinuses drain into one or two efferent lymphatic vessels (efferent = to carry away), which are wider and fewer in number than afferent vessels. They contain valves that open away from the center of the lymph node to convey lymph, antibodies secreted by plasma cells, and activated T cells out of the node. Efferent lymphatic vessels emerge from one side of the lymph node at a slight depression called a hilum (HI-lum). Blood vessels also enter and leave the node at the hilum.

Lymph nodes function as a type of filter. As lymph enters one end of a lymph node, foreign substances are trapped by the reticular fibers within the sinuses of the lymph node. Then macrophages destroy some foreign substances by phagocytosis while lymphocytes destroy others by immune responses. The filtered lymph then leaves the other end of the lymph node.
Spleen

The oval spleen is the largest single mass of lymphatic tissue in the body, measuring about 12 cm (5 in.) in length (Figure 22.7a). It is located in the left hypochondriac region between the stomach and diaphragm. The superior surface of the spleen is smooth and convex and conforms to the concave surface of the diaphragm. Neighboring organs make indentations in the visceral surface of the spleen—the gastric impression (stomach), the renal impression (left kidney), and the colic impression (left colic flexure of large intestine). Like lymph nodes, the spleen has a hilum. Through it pass the splenic artery, splenic vein, and efferent lymphatic vessels.

A capsule of dense connective tissue surrounds the spleen and is covered in turn by a serous membrane, the visceral

Figure 22.7 Structure of the spleen. (See Tortora, A Photographic Atlas of the Human Body, Second Edition, Figure 7.3a.)

After birth, what are the main functions of the spleen?
peritoneum. Trabeculae extend inward from the capsule. The capsule plus trabeculae, reticular fibers, and fibroblasts constitute the stroma of the spleen; the parenchyma of the spleen consists of two different kinds of tissue called white pulp and red pulp (Figure 22.7b, c). White pulp is lymphatic tissue, consisting mostly of lymphocytes and macrophages arranged around branches of the splenic artery called central arteries. The red pulp consists of blood-filled venous sinuses and cords of splenic tissue called splenic (Billroth’s) cords. Splenic cords consist of red blood cells, macrophages, lymphocytes, plasma cells, and granulocytes. Veins are closely associated with the red pulp.

Blood flowing into the spleen through the splenic artery enters the central arteries of the white pulp. Within the white pulp, B cells and T cells carry out immune functions, similar to lymph nodes, while spleen macrophages destroy blood-borne pathogens by phagocytosis. Within the red pulp, the spleen performs three functions related to blood cells: (1) removal by macrophages of ruptured, worn out, or defective blood cells and platelets; (2) storage of platelets, up to one-third of the body’s supply; and (3) production of blood cells (hemopoiesis) during fetal life.

**CLINICAL CONNECTION Ruptured Spleen**

The spleen is the organ most often damaged in cases of abdominal trauma. Severe blows over the inferior left chest or superior abdomen can fracture the protecting ribs. Such crushing injury may result in a ruptured spleen, which causes significant hemorrhage and shock. Prompt removal of the spleen, called a splenectomy, is needed to prevent death due to bleeding. Other structures, particularly red bone marrow and the liver, can take over some functions normally carried out by the spleen. Immune functions, however, decrease in the absence of a spleen. The spleen’s absence also places the patient at higher risk for sepsis (a blood infection) due to loss of the filtering and phagocytic functions of the spleen. To reduce the risk of sepsis, patients who have undergone a splenectomy take prophylactic (preventive) antibiotics before any invasive procedures.

**Lymphatic Nodules**

Lymphatic nodules (follicles) are egg-shaped masses of lymphatic tissue that are not surrounded by a capsule. Because they are scattered throughout the lamina propria (connective tissue) of mucous membranes lining the gastrointestinal, urinary, and reproductive tracts and the respiratory airways, lymphatic nodules in these areas are also referred to as mucosa-associated lymphatic tissue (MALT).

Although many lymphatic nodules are small and solitary, some occur in multiple large aggregations in specific parts of the body. Among these are the tonsils in the pharyngeal region and the aggregated lymphatic follicles (Peyer’s patches) in the ileum of the small intestine. Aggregations of lymphatic nodules also occur in the appendix. Usually there are five tonsils, which form a ring at the junction of the oral cavity and oropharynx and at the junction of the nasal cavity and nasopharynx (see Figure 23.2b). The tonsils are strategically positioned to participate in immune responses against inhaled or ingested foreign substances. The single pharyngeal tonsil (fa-RIN-jē-al) or adenoid is embedded in the posterior wall of the nasopharynx. The two palatine tonsils (PAL-a-tīn) lie at the posterior region of the oral cavity, one on either side; these are the tonsils commonly removed in a tonsillectomy. The paired lingual tonsils (LIN-gwal), located at the base of the tongue, may also require removal during a tonsillectomy.

**CHECKPOINT**

1. How are interstitial fluid and lymph similar, and how do they differ?
2. How do lymphatic vessels differ in structure from veins?
3. Diagram the route of lymph circulation.
4. What is the role of the thymus in immunity?
5. What functions do lymph nodes, the spleen, and the tonsils serve?

**DEVELOPMENT OF LYMPHATIC TISSUES**

- **OBJECTIVE**

  Describe the development of lymphatic tissues.

Lymphatic tissues begin to develop by the end of the fifth week of embryonic life. Lymphatic vessels develop from lymph sacs that arise from developing veins, which are derived from mesoderm.

The first lymph sacs to appear are the paired jugular lymph sacs at the junction of the internal jugular and subclavian veins (Figure 22.8). From the jugular lymph sacs, lymphatic capillary plexuses spread to the thorax, upper limbs,

![Figure 22.8 Development of lymphatic tissues.](image)

**When do lymphatic tissues begin to develop?**
The skin and mucous membranes of the body are the first line of defense against pathogens. These structures provide both physical and chemical barriers that discourage pathogens and foreign substances from penetrating the body and causing disease. With its many layers of closely packed, keratinized cells, the outer epithelial layer of the skin—the epidermis—provides a formidable physical barrier to the entrance of microbes (see Figure 5.1 on page 148). In addition, periodic shedding of epidermal cells helps remove microbes at the skin surface. Bacteria rarely penetrate the intact surface of healthy epidermis. If this surface is broken by cuts, burns, or punctures, however, pathogens can penetrate the epidermis and invade adjacent tissues or circulate in the blood to other parts of the body.

The epithelial layer of mucous membranes, which line body cavities, secretes a fluid called mucus that lubricates and moistens the cavity surface. Because mucus is slightly viscous, it traps many microbes and foreign substances. The mucous membrane of the nose has mucus-coated hairs that trap and filter microbes, dust, and pollutants from inhaled air. The mucous membrane of the upper respiratory tract contains cilia, microscopic hairlike projections on the surface of the epithelial cells. The waving action of cilia propels inhaled dust and microbes that have become trapped in mucus toward the throat. Coughing and sneezing accelerate movement of mucus and its entrapped pathogens out of the body. Swallowing mucus sends pathogens to the stomach where gastric juice destroys them.

Other fluids produced by various organs also help protect epithelial surfaces of the skin and mucous membranes. The lacrimal apparatus (LAK-ri-mal) of the eyes (see Figure 17.6 on page 606) manufactures and drains away tears in response to irritants. Blinking spreads tears over the surface of the eyeball, and the continual washing action of tears helps to dilute microbes and keep them from settling on the surface of the eye. Tears also contain lysozyme, an enzyme capable of breaking down the cell walls of certain bacteria. Besides tears, lysozyme is present in saliva, perspiration, nasal secretions, and tissue fluids. Saliva, produced by the salivary glands, washes microbes from the surfaces of the teeth and from the mucous membrane of the mouth, much as tears wash the eyes. The flow of saliva reduces colonization of the mouth by microbes.

The cleansing of the urethra by the flow of urine retards microbial colonization of the urinary system. Vaginal secretions likewise move microbes out of the body in females. Defecation and vomiting also expel microbes. For example, in response to some microbial toxins, the smooth muscle of the lower gastrointestinal tract contracts vigorously; the resulting diarrhea rapidly expels many of the microbes.

Certain chemicals also contribute to the high degree of resistance of the skin and mucous membranes to microbial invasion. Sebaceous (oil) glands of the skin secrete an oily substance called sebum that forms a protective film over the surface of the skin. The unsaturated fatty acids in sebum inhibit the growth of certain pathogenic bacteria and fungi. The acidity of the skin (pH 3–5) is caused in part by the secretion of fatty acids and lactic acid. Perspiration helps flush microbes from the surface of the skin. Gastric juice, produced by the glands of the stomach, is a mixture of hydrochloric acid, enzymes, and mucus. The strong acidity of gastric juice (pH 1.2–3.0) destroys many bacteria and most bacterial toxins. Vaginal secretions also are slightly acidic, which discourages bacterial growth.
Second Line of Defense: Internal Defenses

When pathogens penetrate the physical and chemical barriers of the skin and mucous membranes, they encounter a second line of defense: internal antimicrobial substances, phagocytes, natural killer cells, inflammation, and fever.

Antimicrobial Substances

There are four main types of antimicrobial substances that discourage microbial growth: interferons, complement, iron-binding proteins, and antimicrobial proteins.

1. Lymphocytes, macrophages, and fibroblasts infected with viruses produce proteins called interferons (in-ter-FER-ons), or IFNs. Once released by virus-infected cells, IFNs diffuse to uninfected neighboring cells, where they induce synthesis of antiviral proteins that interfere with viral replication. Although IFNs do not prevent viruses from attaching to and penetrating host cells, they do stop replication. Viruses can cause disease only if they can replicate within body cells. IFNs are an important defense against infection by many different viruses. The three types of interferon are alpha-, beta-, and gamma-IFN.

2. A group of normally inactive proteins in blood plasma and on plasma membranes makes up the complement system. When activated, these proteins “complement” or enhance certain immune reactions (see page 860). The complement system causes cytolysis (bursting) of microbes, promotes phagocytosis, and contributes to inflammation.

3. Iron-binding proteins inhibit the growth of certain bacteria by reducing the amount of available iron. Examples include transferrin (found in blood and tissue fluids), lactoferrin (found in milk, saliva, and mucus), ferritin (found in the liver, spleen, and red bone marrow), and hemoglobin (found in red blood cells).

4. Antimicrobial proteins (AMPs) are short peptides that have a broad spectrum of antimicrobial activity. Examples of AMPs are dermicidin (produced by sweat glands), defensins and cathelicidins (produced by neutrophils, macrophages, and epithelia), and thrombocidin (produced by platelets). Besides killing a wide range of microbes, AMPs can attract dendritic cells and mast cells, which participate in immune responses. Interestingly enough, microbes exposed to AMPs do not appear to develop resistance, as often happens with antibiotics.

Natural Killer Cells and Phagocytes

When microbes penetrate the skin and mucous membranes or bypass the antimicrobial substances in blood, the next nonspecific defense consists of natural killer cells and phagocytes. About 5–10% of lymphocytes in the blood are natural killer (NK) cells. They are also present in the spleen, lymph nodes, and red bone marrow. NK cells lack the membrane molecules that identify B and T cells, but they have the ability to kill a wide variety of infected body cells and certain tumor cells. NK cells attack any body cells that display abnormal or unusual plasma membrane proteins.

The binding of NK cells to a target cell, such as an infected human cell, causes the release of granules containing toxic substances from NK cells. Some granules contain a protein called perforin that inserts into the plasma membrane of the target cell and creates channels (perforations) in the membrane. As a result, extracellular fluid flows into the target cell and the cell bursts, a process called cytolysis (si-TO-l-i-sis; cyto- = cell; -lysis = loosening). Other granules of NK cells release granzymes, which are protein-digesting enzymes that induce the target cell to undergo apoptosis, or self-destruction. This type of attack kills infected cells, but not the microbes inside the cells; the released microbes, which may or may not be intact, can be destroyed by phagocytes.

Phagocytes (phago- = eat; -cytes = cells) are specialized cells that perform phagocytosis (-osis = process), the ingestion of microbes or other particles such as cellular debris (see Figure 3.13 on page 75). The two major types of phagocytes are neutrophils and macrophages (MAK-ro-fä-jez). When an infection occurs, neutrophils and monocytes migrate to the infected area. During this migration, the monocytes enlarge and develop into actively phagocytic macrophages called wandering macrophages. Other macrophages, called fixed macrophages, stand guard in specific tissues. Among the fixed macrophages are histiocytes (connective tissue macrophages), stellate reticuloendothelial cells (Kupffer cells) in the liver, alveolar macrophages in the lungs, microglia in the nervous system, and tissue macrophages in the spleen, lymph nodes, and red bone marrow. In addition to being an innate defense mechanism, phagocytosis plays a vital role in adaptive immunity, as discussed later in the chapter.

CLINICAL CONNECTION Microbial Evasion of Phagocytosis

Some microbes, such as the bacteria that cause pneumonia, have extracellular structures called capsules that prevent adherence. This makes it physically difficult for phagocytes to engulf the microbes. Other microbes, such as the toxin-producing bacteria that cause one kind of food poisoning, may be ingested but not killed; instead, the toxins they produce (leukocidins) may kill the phagocytes by causing the release of the phagocyte’s own lysosomal enzymes into its cytoplasm. Still other microbes—such as the bacteria that cause tuberculosis—inhibit fusion of phagosomes and lysosomes and thus prevent exposure of the microbes to lysosomal enzymes. These bacteria apparently can also use chemicals in their cell walls to counter the effects of lethal oxidants produced by phagocytes. Subsequent multiplication of the microbes within phagosomes may eventually destroy the phagocyte.
Phagocytosis occurs in five phases: chemotaxis, adherence, ingestion, digestion, and killing (Figure 22.9):

1. **Chemotaxis.** Phagocytosis begins with chemotaxis, a chemically stimulated movement of phagocytes to a site of damage. Chemicals that attract phagocytes might come from invading microbes, white blood cells, damaged tissue cells, or activated complement proteins.

2. **Adherence.** Attachment of the phagocyte to the microbe or other foreign material is termed adherence. The binding of complement proteins to the invading pathogen enhances adherence.

3. **Ingestion.** The plasma membrane of the phagocyte extends projections, called pseudopods, that engulf the microbe in a process called ingestion. When the pseudopods meet, they fuse, surrounding the microorganism with a sac called a phagosome.

4. **Digestion.** The phagosome enters the cytoplasm and merges with lysosomes to form a single, larger structure called a phagolysosome. The lysosome contributes lysozyme, which breaks down microbial cell walls, and other digestive enzymes that degrade carbohydrates, proteins, lipids, and nucleic acids. The phagocyte also forms lethal oxidants, such as superoxide anion (O$_2^-$), hypochlorite anion (OCl$^-$), and hydrogen peroxide (H$_2$O$_2$), in a process called an oxidative burst.

5. **Killing.** The chemical onslaught provided by lysozyme, digestive enzymes, and oxidants within a phagolysosome quickly kills many types of microbes. Any materials that cannot be degraded further remain in structures called residual bodies.

**Inflammation**

Inflammation is a nonspecific, defensive response of the body to tissue damage. Among the conditions that may produce inflammation are pathogens, abrasions, chemical irritations, distortion or disturbances of cells, and extreme temperatures. The four characteristic signs and symptoms of inflammation are **redness, pain, heat, and swelling.** Inflammation can also cause the **loss of function** in the injured area (for example, the inability to detect sensations), depending on the site and extent of the injury. Inflammation is an attempt to dispose of microbes, toxins, or foreign material at the site of injury, to prevent their spread to other tissues, and to prepare the site for tissue repair in an attempt to restore tissue homeostasis.

Because inflammation is one of the body’s nonspecific defense mechanisms, the response of a tissue to a cut is similar to the response to damage caused by burns, radiation, or bacterial or viral invasion. In each case, the inflammatory response has three basic stages: (1) vasodilation and increased permeability of blood vessels, (2) emigration (movement) of phagocytes from the blood into interstitial fluid, and, ultimately, (3) tissue repair.

**VASODILATION AND INCREASED PERMEABILITY OF BLOOD VESSELS**

Two immediate changes occur in the blood vessels in a region of tissue injury: vasodilation (increase in the diameter) of arterioles and increased permeability of capillaries (Figure 22.10). Increased permeability means that substances normally retained in blood are permitted to pass from the blood vessels. Vasodilation allows more blood to flow through the damaged area, and increased permeability permits defensive pro-
teins such as antibodies and clotting factors to enter the injured area from the blood. The increased blood flow also helps remove microbial toxins and dead cells.

Among the substances that contribute to vasodilation, increased permeability, and other aspects of the inflammatory response are the following:

- **Histamine.** In response to injury, mast cells in connective tissue and basophils and platelets in blood release histamine. Neutrophils and macrophages attracted to the site of injury also stimulate the release of histamine, which causes vasodilation and increased permeability of blood vessels.

- **Kinins.** These polypeptides, formed in blood from inactive precursors called kininogens, induce vasodilation and increased permeability and serve as chemotactic agents for phagocytes. An example of a kinin is bradykinin.

- **Prostaglandins (PGs).** These lipids, especially those of the E series, are released by damaged cells and intensify the effects of histamine and kinins. PGs also may stimulate the emigration of phagocytes through capillary walls.

- **Leukotrienes (LTs).** Produced by basophils and mast cells, LTs cause increased permeability; they also function in adherence of phagocytes to pathogens and as chemotactic agents that attract phagocytes.

- **Complement.** Different components of the complement system stimulate histamine release, attract neutrophils by chemotaxis, and promote phagocytosis; some components can also destroy bacteria.

Dilation of arterioles and increased permeability of capillaries produce three of the signs and symptoms of inflammation: heat, redness (erythema), and swelling (edema). Heat and redness result from the large amount of blood that accumulates in the damaged area. As the local temperature rises slightly, metabolic reactions proceed more rapidly and release additional heat. Edema results from increased permeability of blood vessels, which permits more fluid to move from blood plasma into tissue spaces.

Pain is a prime symptom of inflammation. It results from injury to neurons and from toxic chemicals released by microbes. Kinins affect some nerve endings, causing much of the pain associated with inflammation. Prostaglandins intensify and prolong the pain associated with inflammation. Pain may also be due to increased pressure from edema.

The increased permeability of capillaries allows leakage of blood-clotting factors into tissues. The clotting sequence is set into motion, and fibrinogen is ultimately converted to an insoluble, thick mesh of fibrin threads that localizes and traps invading microbes and blocks their spread.

**Emigration of Phagocytes** Within an hour after the inflammatory process starts, phagocytes appear on the scene. As large amounts of blood accumulate, neutrophils begin to stick to the inner surface of the endothelium (lining) of blood vessels (Figure 22.10). Then the neutrophils begin to squeeze through the wall of the blood vessel to reach the damaged area. This process, called emigration, depends on chemotaxis. Neutrophils attempt to destroy the invading microbes by phagocytosis. A steady stream of neutrophils is ensured by the production and release of additional cells from red bone marrow. Such an increase in white blood cells in the blood is termed leukocytosis.

Although neutrophils predominate in the early stages of infection, they die off rapidly. As the inflammatory response continues, monocytes follow the neutrophils into the infected area. Once in the tissue, monocytes transform into wandering macrophages that add to the phagocytic activity of the fixed macrophages already present. True to their name, macrophages are much more potent phagocytes than neutrophils. They are large enough to engulf damaged tissue, worn-out neutrophils, and invading microbes.

Eventually, macrophages also die. Within a few days, a pocket of dead phagocytes and damaged tissue forms; this collection of dead cells and fluid is called pus. Pus formation occurs in most inflammatory responses and usually continues until the infection subsides. At times, pus reaches the surface of the body or drains into an internal cavity and is dispersed; on other occasions the pus remains even after the infection is terminated. In this case, the pus is gradually destroyed over a period of days and is absorbed.
Cells and tissues that carry out immune responses.

**Fever**

Fever is an abnormally high body temperature that occurs because the hypothalamic thermostat is reset. It commonly occurs during infection and inflammation. Many bacterial toxins elevate body temperature, sometimes by triggering release of fever-causing cytokines such as interleukin-1 from macrophages. Elevated body temperature intensifies the effects of interferons, inhibits the growth of some microbes, and speeds up body reactions that aid repair.

The ability of the body to defend itself against specific invading agents such as bacteria, toxins, viruses, and foreign tissues is called adaptive (specific) immunity. Substances that are recognized as foreign and provoke immune responses are called antigens (Ags). Two properties distinguish adaptive immunity from innate immunity: (1) specificity for particular foreign molecules (antigens), which also involves distinguishing self from nonself molecules, and (2) memory for most previously encountered antigens so that a second encounter prompts an even more rapid and vigorous response. The branch of science that deals with the responses of the body when challenged by antigens is called immunology (im’-ú-NOL-ō-jē; immuno- = free from service or exempt; -logy = study of). The immune system includes the cells and tissues that carry out immune responses.
Maturation of T Cells and B Cells

Adaptive immunity involves lymphocytes called B cells and T cells. Both develop in primary lymphatic organs (red bone marrow and the thymus) from pluripotent stem cells that originate in red bone marrow (see Figure 19.3 on page 694). B cells complete their development in red bone marrow, a process that continues throughout life. T cells develop from pre-T cells that migrate from red bone marrow into the thymus, where they mature (Figure 22.11). Most T cells arise before puberty, but they continue to mature and leave the thymus throughout life. B cells and T cells are named based on where they mature. In birds, B cells mature in an organ called the bursa of Fabricius. Although

Figure 22.11 B cells and pre-T cells arise from pluripotent stem cells in red bone marrow. B cells and T cells develop in primary lymphatic tissues (red bone marrow and the thymus) and are activated in secondary lymphatic organs and tissues (lymph nodes, spleen, and lymphatic nodules). Once activated, each type of lymphocyte forms a clone of cells that can recognize a specific antigen. For simplicity, antigen receptors, CD4 proteins, and CD8 proteins are not shown in the plasma membranes of the cells of the lymphocyte clones.

The two types of adaptive immunity are cell-mediated immunity and antibody-mediated immunity.

Which type of T cell participates in both cell-mediated and antibody-mediated immune responses?
this organ is not present in humans, the term B cell is still used, but the letter B stands for bursa equivalent, which is the red bone marrow since that is the location in humans where B cells mature. T cells are so named because they mature in the thymus.

Before T cells leave the thymus or B cells leave red bone marrow, they develop immunocompetence, the ability to carry out adaptive immune responses. This means that B cells and T cells begin to make several distinctive proteins that are inserted into their plasma membranes. Some of these proteins function as antigen receptors—molecules capable of recognizing specific antigens (Figure 22.11).

There are two major types of mature T cells that exit the thymus: helper T cells and cytotoxic T cells (Figure 22.11). Helper T cells are also known as CD4 T cells, which means that, in addition to antigen receptors, their plasma membranes include a protein called CD4. Cytotoxic T cells are also referred to as CD8 T cells because their plasma membranes not only contain antigen receptors but also a protein known as CD8. As we will see later in this chapter, these two types of T cells have very different functions.

Types of Adaptive Immunity

There are two types of adaptive immunity: cell-mediated immunity and antibody-mediated immunity. Both types of adaptive immunity are triggered by antigens. In cell-mediated immunity, cytotoxic T cells directly attack invading antigens. In antibody-mediated immunity, B cells transform into plasma cells, which synthesize and secrete specific proteins called antibodies (Abs) or immunoglobulins (im′-ū-nō-GLOB-ū-lins). A given antibody can bind to and inactivate a specific antigen. Helper T cells aid the immune responses of both cell-mediated and antibody-mediated immunity.

Cell-mediated immunity is particularly effective against (1) intracellular pathogens, which include any viruses, bacteria, or fungi that are inside cells; (2) some cancer cells; and (3) foreign tissue transplants. Thus, cell-mediated immunity always involves cells attacking cells. Antibody-mediated immunity works mainly against extracellular pathogens, which include any viruses, bacteria, or fungi that are in body fluids outside cells. Since antibody-mediated immunity involves antibodies that bind to antigens in body humors or fluids (such as blood and lymph), it is also referred to as humoral immunity.

In most cases, when a particular antigen initially enters the body, there is only a small group of lymphocytes with the correct antigen receptors to respond to that antigen; this small group of cells includes a few helper T cells, cytotoxic T cells, and B cells. Depending on its location, a given antigen can provoke both types of adaptive immune responses. This is due to the fact that when a specific antigen invades the body, there are usually many copies of that antigen spread throughout the body’s tissues and fluids. Some copies of the antigen may be present inside body cells (which provokes a cell-mediated immune response by cytotoxic T cells), while other copies of the antigen may be present in extracellular fluid (which provokes an antibody-mediated immune response by B cells). Thus, cell-mediated and antibody-mediated immune responses often work together to get rid of the large number of copies of a particular antigen from the body.

Clonal Selection: The Principle

As you just learned, when a specific antigen is present in the body, there are usually many copies of that antigen located throughout the body’s tissues and fluids. The numerous copies of the antigen initially outnumber the small group of helper T cells, cytotoxic T cells, and B cells with the correct antigen receptors to respond to that antigen. Therefore, once each of these lymphocytes encounters a copy of the antigen and receives stimulatory cues, it subsequently undergoes clonal selection. Clonal selection is the process by which a lymphocyte proliferates (divides) and differentiates (forms more highly specialized cells) in response to a specific antigen. The result of clonal selection is the formation of a population of identical cells, called a clone, that can recognize the same specific antigen as the original lymphocyte (Figure 22.11). Before the first exposure to a given antigen, only a few lymphocytes are able to recognize it, but once clonal selection occurs, there are thousands of lymphocytes that can respond to that antigen. Clonal selection of lymphocytes occurs in the secondary lymphatic organs and tissues. The swollen tonsils or lymph nodes in your neck you experienced the last time you were sick were probably caused by clonal selection of lymphocytes participating in an immune response.

A lymphocyte that undergoes clonal selection gives rise to two major types of cells in the clone: effector cells and memory cells. The thousands of effector cells of a lymphocyte clone carry out immune responses that ultimately result in the destruction or inactivation of the antigen. Effector cells include active helper T cells, which are part of a helper T cell clone; active cytotoxic T cells, which are part of a cytotoxic T cell clone; and plasma cells, which are part of a B cell clone. Most effector cells eventually die after the immune response has been completed.

Memory cells do not actively participate in the initial immune response to the antigen. However, if the same antigen enters the body again in the future, the thousands of memory cells of a lymphocyte clone are available to initiate a far swifter reaction than occurred during the first invasion. The memory cells respond to the antigen by proliferating and differentiating into more effector cells and more memory cells. Consequently, the second response to the antigen is usually so fast and so vigorous that the antigen is destroyed before any signs or symptoms of disease can occur. Memory cells include memory helper T cells, which are part of a helper T cell clone; memory cytotoxic T cells, which are part of a cytotoxic T cell clone; and memory B cells, which are part of a B cell clone. Most memory cells do not die at the end of an immune response. Instead, they have long life spans (often lasting for decades). The functions of ef-
Antigens and Antigen Receptors

Antigens have two important characteristics: immunogenicity and reactivity. Immunogenicity (im-ū-nō-je-N-I-tē′; -genic = producing) is the ability to provoke an immune response by stimulating the production of specific antibodies, the proliferation of specific T cells, or both. The term antigen derives from its function as an antibody generator. Reactivity is the ability of the antigen to react specifically with the antibodies or cells it provoked. Strictly speaking, immunologists define antigens as substances that have reactivity; substances with both immunogenicity and reactivity are considered complete antigens. Commonly, however, the term antigen implies both immunogenicity and reactivity, and we use the word in this way.

Entire microbes or parts of microbes may act as antigens. Chemical components of bacterial structures such as flagella, capsules, and cell walls are antigenic, as are bacterial toxins. Nonmicrobial examples of antigens include chemical components of pollen, egg white, incompatible blood cells, and transplanted tissues and organs. The huge variety of antigens in the environment provides myriad opportunities for provoking immune responses. Typically, just certain small parts of a large antigen molecule act as the triggers for immune responses. These small parts are called epitopes (EP-i-tōps), or antigenic determinants (Figure 22.12). Most antigens have many epitopes, each of which induces production of a specific antibody or activates a specific T cell.

Antigens that get past the innate defenses generally follow one of three routes into lymphatic tissue: (1) Most antigens that enter the bloodstream (for example, through an injured blood vessel) are trapped as they flow through the spleen. (2) Antigens that penetrate the skin enter lymphatic vessels and lodge in lymph nodes. (3) Antigens that penetrate mucous membranes are entrapped by mucosa-associated lymphatic tissue (MALT).

Chemical Nature of Antigens

Antigens are large, complex molecules. Most often, they are proteins. However, nucleic acids, lipoproteins, glycoproteins, and certain large polysaccharides may also act as antigens. Complete antigens usually have large molecular weights of 10,000 daltons or more, but large molecules that have simple, repeating subunits—for example, cellulose and most plastics—are not usually antigenic. This is why plastic materials can be used in artificial heart valves or joints.

A smaller substance that has reactivity but lacks immunogenicity is called a hapten (HAP-ten = to grasp). A hapten can stimulate an immune response only if it is attached to a larger carrier molecule. An example is the small lipid toxin in poison ivy, which triggers an immune response after combining with a body protein. Likewise, some drugs, such as penicillin, may combine with proteins in the body to form immunogenic complexes. Such hapten-stimulated immune responses are responsible for some allergic reactions to drugs and other substances in the environment (see page 868).

As a rule, antigens are foreign substances; they are not usually part of body tissues. However, sometimes the immune system fails to distinguish “friend” (self) from “foe” (nonself). The result is an autoimmune disorder (see page 868) in which self-molecules or cells are attacked as though they were foreign.

Diversity of Antigen Receptors

An amazing feature of the human immune system is its ability to recognize and bind to at least a billion (10^9) different epitopes. Before a particular antigen ever enters the body, T cells and B cells that can recognize and respond to that intruder are ready and waiting. Cells of the immune system can even recognize artificially made molecules that do not exist in nature. The basis for the ability to recognize so many epitopes is an equally large diversity of antigen receptors. Given that human cells contain only about 35,000 genes, how could a billion or more different antigen receptors possibly be generated?

The answer to this puzzle turned out to be simple in concept. The diversity of antigen receptors in both B cells and T cells is the result of shuffling and rearranging a few hundred versions of several small gene segments. This process is called genetic recombination. The gene segments are put together in different combinations as the lymphocytes are developing from stem cells in red bone marrow and the thymus. The situation is similar to shuffling a deck of 52 cards and then dealing out three cards. If you did this over and over, you could generate many more than 52 different sets of three cards. Because of genetic recombination, each B cell or T cell has a unique set of gene segments that codes for its unique antigen receptor. After transcription and translation, the receptor molecules are inserted into the plasma membrane.
Major Histocompatibility Complex Antigens

Located in the plasma membrane of body cells are “self-antigens,” the major histocompatibility complex (MHC) antigens. These transmembrane glycoproteins are also called human leukocyte antigens (HLA) because they were first identified on white blood cells. Unless you have an identical twin, your MHC antigens are unique. Thousands to several hundred thousand MHC molecules mark the surface of each of your body cells except red blood cells. Although MHC antigens are the reason that tissues may be rejected when they are transplanted from one person to another, their normal function is to help T cells recognize that an antigen is foreign, not self. Such recognition is an important first step in any adaptive immune response.

The two types of major histocompatibility complex antigens are class I and class II. Class I MHC (MHC-I) molecules are built into the plasma membranes of all body cells except red blood cells. Class II MHC (MHC-II) molecules appear on the surface of antigen-presenting cells (described in the next section).

Pathways of Antigen Processing

For an immune response to occur, B cells and T cells must recognize that a foreign antigen is present. B cells can recognize and bind to antigens in lymph, interstitial fluid, or blood plasma. T cells only recognize fragments of antigenic proteins that are processed and presented in a certain way. In antigen processing, antigenic proteins are broken down into peptide fragments that then associate with MHC molecules. Next the antigen-MHC complex is inserted into the plasma membrane of a body cell. The insertion of the complex into the plasma membrane is called antigen presentation. When a peptide fragment comes from a self-protein, T cells ignore the antigen-MHC complex. However, if the peptide fragment comes from a foreign protein, T cells recognize the antigen-MHC complex as an intruder, and an immune response takes place. Antigen processing and presentation occurs in two ways, depending on whether the antigen is located outside or inside body cells.

Processing of Exogenous Antigens

Foreign antigens that are present in fluids outside body cells are termed exogenous antigens. They include intruders such as bacteria and bacterial toxins, parasitic worms, inhaled pollen and dust, and viruses that have not yet infected a body cell. A special class of cells called antigen-presenting cells (APCs) process and present exogenous antigens. APCs include dendritic cells, macrophages, and B cells. They are strategically located in places where antigens are likely to penetrate the innate defenses and enter the body, such as the epidermis and dermis of the skin (Langerhans cells are a type of dendritic cell); mucous membranes that line the respiratory, gastrointestinal, urinary, and reproductive tracts; and lymph nodes. After processing and presenting an antigen, APCs migrate from tissues via lymphatic vessels to lymph nodes.

The steps in the processing and presenting of an exogenous antigen by an antigen-presenting cell occur as follows (Figure 22.13):

1. **Ingestion of the antigen.** Antigen-presenting cells ingest exogenous antigens by phagocytosis or endocytosis. Ingestion could occur almost anywhere in the body that invaders, such as microbes, have penetrated the innate defenses.
2. **Digestion of antigen into peptide fragments.** Within the phagosome or endosome protein-digesting enzymes split large antigens into short peptide fragments.
3. **Synthesis of MHC-II molecules.** At the same time, the APC synthesizes MHC-II molecules at the endoplasmic reticulum (ER).
4. **Packaging of MHC-II molecules.** Once synthesized, the MHC-II molecules are packaged into vesicles.
5. **Fusion of vesicles.** The vesicles containing antigen peptide fragments and MHC-II molecules merge and fuse.
6. **Binding of peptide fragments to MHC-II molecules.** After fusion of the two types of vesicles, antigen peptide fragments bind to MHC-II molecules.
7. **Insertion of antigen–MHC-II complexes into the plasma membrane.** The combined vesicle that contains antigen–MHC-II complexes undergoes exocytosis. As a result, the antigen–MHC-II complexes are inserted into the plasma membrane.

After processing an antigen, the antigen-presenting cell migrates to lymphatic tissue to present the antigen to T cells. Within lymphatic tissue, a small number of T cells that have compatibly shaped receptors recognize and bind to the antigen fragment–MHC-II complex, triggering an adaptive immune response. The presentation of exogenous antigen together with MHC-II molecules by antigen-presenting cells informs T cells that intruders are present in the body and that combative action should begin.

Processing of Endogenous Antigens

Foreign antigens that are present inside body cells are termed endogenous antigens. Such antigens may be viral proteins produced after a virus infects the cell and takes over the cell’s metabolic machinery, toxins produced from intracellular bacteria, or abnormal proteins synthesized by a cancerous cell.

The steps in the processing and presenting of an endogenous antigen by an infected body cell occur as follows (Figure 22.14):

1. **Digestion of antigen into peptide fragments.** Within the infected cell, protein-digesting enzymes split the endogenous antigen into short peptide fragments.
2. **Synthesis of MHC-I molecules.** At the same time, the infected cell synthesizes MHC-I molecules at the endoplasmic reticulum (ER).
3. **Binding of peptide fragments to MHC-I molecules.** The antigen peptide fragments enter the ER and then bind to MHC-I molecules.
**Figure 22.13** Processing and presenting of exogenous antigen by an antigen-presenting cell (APC).

Fragments of exogenous antigens are processed and then presented with MHC-II molecules on the surface of an antigen-presenting cell (APC).

5. Vesicle undergoes exocytosis and antigen-MHC-I complexes are inserted into plasma membrane

Infected body cells present endogenous antigens in association with MHC-I molecules

**Question:** What are some examples of endogenous antigens?
Cytokines

Cytokines are small protein hormones that stimulate or inhibit many normal cell functions, such as cell growth and differentiation. Lymphocytes and antigen-presenting cells secrete cytokines, as do fibroblasts, endothelial cells, monocytes, hepatocytes, and kidney cells. Some cytokines stimulate proliferation of progenitor blood cells in red bone marrow. Others regulate activities of cells involved in innate defenses or adaptive immune responses, as described in Table 22.2.

</tbody>
</table>
A cell-mediated immune response begins with activation of a small number of T cells by a specific antigen. Once a T cell has been activated, it undergoes clonal selection. Recall that clonal selection is the process by which a lymphocyte proliferates (divides several times) and differentiates (forms more highly specialized cells) in response to a specific antigen. The result of clonal selection is the formation of a clone of cells that can recognize the same antigen as the original lymphocyte (see Figure 22.11). Some of the cells of a T cell clone become effector cells, while other cells of the clone become memory cells. The effector cells of a T cell clone carry out immune responses that ultimately result in elimination of the intruder.

**Activation of T Cells**

At any given time, most T cells are inactive. As you learned in the last section, antigen receptors on the surface of T cells, called T-cell receptors (TCRs), recognize and bind to specific foreign antigen fragments that are presented in antigen–MHC complexes. There are millions of different T cells; each has its own unique TCRs that can recognize a specific antigen–MHC complex. When an antigen enters the body, only a few T cells have TCRs that can recognize and bind to the antigen. Antigen recognition also involves other surface proteins on T cells, the CD4 or CD8 proteins. These proteins interact with the MHC antigens and help maintain the TCR-MHC coupling. For this reason, they are referred to as coreceptors. Antigen recognition by a TCR with CD4 or CD8 proteins is the first signal in activation of a T cell.

A T cell becomes activated only if it binds to the foreign antigen and at the same time receives a second signal, a process known as costimulation. Of the more than 20 known costimulators, some are cytokines, such as interleukin-2. Other costimulators include pairs of plasma membrane molecules, one on the surface of the T cell and a second on the surface of an antigen-presenting cell, that enable the two cells to adhere to one another for a period of time.

The need for two signals to activate a T cell is a little like starting and driving a car: When you insert the correct key (antigen) in the ignition (TCR) and turn it, the car starts (recognition of specific antigen), but it cannot move forward until you move the gear shift into drive (costimulation). The need for costimulation may prevent immune responses from occurring accidentally. Different costimulators affect the activated T cell in different ways, just as shifting a car into reverse has a different effect than shifting it into drive. Moreover, recognition (antigen binding to a receptor) without costimulation leads to a prolonged state of inactivity called anergy in both T cells and B cells. Anergy is rather like leaving a car in neutral gear with its engine running until it’s out of gas!

Once a T cell has received these two signals (antigen recognition and costimulation), it is activated. An activated T cell subsequently undergoes clonal selection.

**Activation and Clonal Selection of Helper T Cells**

Most T cells that display CD4 develop into helper T cells, also known as CD4 T cells. Inactive (resting) helper T cells recognize exogenous antigen fragments associated with major histocompatibility complex class II (MHC-II) molecules at the surface of an APC (Figure 22.15). With the aid of the CD4 protein, the T cell binds to the MHC-II molecules and costimulates the T cell for activation. The activated helper T cell then forms a clone of active helper T cells and memory helper T cells.

What are the first and second signals in activation of a T cell?
the helper T cell and APC interact with each other (antigenic recognition), costimulation occurs, and the helper T cell becomes activated.

Once activated, the helper T cell undergoes clonal selection (Figure 22.15). The result is the formation of a clone of helper T cells that consists of active helper T cells and memory helper T cells. Within hours after costimulation, active helper T cells start secreting a variety of cytokines (see Table 22.2). One very important cytokine produced by helper T cells is interleukin-2 (IL-2), which is needed for virtually all immune responses and is the prime trigger of T cell proliferation. IL-2 can act as a costimulator for resting helper T cells or cytotoxic T cells, and it enhances activation and proliferation of T cells, B cells, and natural killer cells. Some actions of interleukin-2 provide a good example of a beneficial positive feedback system. As noted earlier, activation of a helper T cell stimulates it to start secreting IL-2, which then acts in an autocrine manner by binding to IL-2 receptors on the plasma membrane of the cell that secreted it. One effect is stimulation of cell division. As the helper T cells proliferate, a positive feedback effect occurs because they secrete more IL-2, which causes further cell division. IL-2 may also act in a paracrine manner by binding to IL-2 receptors on neighboring helper T cells, cytotoxic T cells, or B cells. If any of these neighboring cells have already become bound to a copy of the same antigen, IL-2 serves as a costimulator.

The memory helper T cells of a helper T cell clone are not active cells. However, if the same antigen enters the body again in the future, memory helper T cells can quickly proliferate and differentiate into more active helper T cells and more memory helper T cells.

Activation and Clonal Selection of Cytotoxic T Cells

Most T cells that display CD8 develop into cytotoxic T cells, also termed CD8 T cells. Cytotoxic T cells recognize foreign antigens combined with major histocompatibility complex class I (MHC-I) molecules on the surface of (1) body cells infected by microbes, (2) some tumor cells, and (3) cells of a tissue transplant (Figure 22.16). Recognition requires the TCR and CD8 protein to maintain the coupling with MHC-I. Following antigenic recognition, costimulation occurs. In order to become activated, cytotoxic T cells require costimulation by interleukin-2 or other cytokines produced by active helper T cells that have already become bound to copies of the same antigen. (Recall that helper T cells are activated by antigen associated with MHC-II molecules.) Thus, maximal activation of cytotoxic T cells requires presentation of antigen associated with both MHC-I and MHC-II molecules.

Once activated, the cytotoxic T cell undergoes clonal selection. The result is the formation of a clone of cytotoxic T cells that consists of active cytotoxic T cells and memory cytotoxic T cells. Active cytotoxic T cells attack other body cells that have been infected with the antigen. Memory cytotoxic T cells do not attack infected body cells. Instead, they can quickly proliferate and differentiate into more active cytotoxic T cells and more memory cytotoxic T cells if the same antigen enters the body at a future time.

Elimination of Invaders

Cytotoxic T cells are the soldiers that march forth to do battle with foreign invaders in cell-mediated immune responses. They leave secondary lymphatic organs and tissues and migrate to seek out and destroy infected target cells, cancer cells, and transplanted cells (Figure 22.17). Cytotoxic T cells recognize and attach to target cells. Then, the cytotoxic T cells deliver a “lethal hit” that kills the target cells.

What is the function of the CD8 protein of a cytotoxic T cell?
Cytotoxic T cells kill infected target body cells much like natural killer cells do. The major difference is that cytotoxic T cells have receptors specific for a particular microbe and thus kill only target body cells infected with one particular type of microbe; natural killer cells can destroy a wide variety of microbe-infected body cells. Cytotoxic T cells have two principal mechanisms for killing infected target cells.

1. Cytotoxic T cells, using receptors on their surfaces, recognize and bind to infected target cells that have microbial antigens displayed on their surface. The cytotoxic T cell then releases granzymes, protein-digesting enzymes that trigger apoptosis (Figure 22.17a). Once the infected cell is destroyed, the released microbes are killed by phagocytes.

2. Alternatively, cytotoxic T cells bind to infected body cells and release two proteins from their granules: perforin and granulysin. Perforin inserts into the plasma membrane of the target cell and creates channels in the membrane (Figure 22.17b). As a result, extracellular fluid flows into the target cell and cytolysis (cell bursting) occurs. Other granules in cytotoxic T cells release granulysin, which enters through the channels and destroys the microbes by creating holes in their plasma membranes. Cytotoxic T cells may also destroy target

Figure 22.17 Activity of cytotoxic T cells. After delivering a “lethal hit,” a cytotoxic T cell can detach and attack another infected target cell displaying the same antigen.

?? In addition to cells infected by microbes, what other types of target cells are attacked by cytotoxic T cells?
cells by releasing a toxic molecule called lymphotoxin, which activates enzymes in the target cell. These enzymes cause the target cell’s DNA to fragment and the cell dies. In addition, cytotoxic T cells secrete gamma-interferon, which attracts and activates phagocytic cells, and macrophage migration inhibition factor, which prevents migration of phagocytes from the infection site. After detaching from a target cell, a cytotoxic T cell can seek out and destroy another target cell.

**Immunological Surveillance**

When a normal cell transforms into a cancerous cell, it often displays novel cell surface components called tumor antigens. These molecules are rarely, if ever, displayed on the surface of normal cells. If the immune system recognizes a tumor antigen as nonself, it can destroy any cancer cells carrying that antigen. Such immune responses, called immunological surveillance, are carried out by cytotoxic T cells, macrophages, and natural killer cells. Immunological surveillance is most effective in eliminating tumor cells due to cancer-causing viruses. For this reason, transplant recipients who are taking immunosuppressive drugs to prevent transplant rejection have an increased incidence of virus-associated cancers. Their risk for other types of cancer is not increased.

**ANTIBODY-MEDIATED IMMUNITY**

**OBJECTIVES**

- Describe the steps in an antibody-mediated immune response.
- List the chemical characteristics and actions of antibodies.
- Explain how the complement system operates.
- Distinguish between a primary response and a secondary response to infection.

The body contains not only millions of different T cells but also millions of different B cells, each capable of responding to a specific antigen. Cytotoxic T cells leave lymphatic tissues to seek out and destroy a foreign antigen, but B cells stay put. In the presence of a foreign antigen, a specific B cell in a lymph node, the spleen, or mucosa-associated lymphatic tissue becomes activated. Then it undergoes clonal selection, forming a clone of plasma cells and memory cells. Plasma cells are the effector cells of a B cell clone; they secrete specific antibodies, which in turn circulate in the lymph and blood to reach the site of invasion.

**Activation and Clonal Selection of B Cells**

During activation of a B cell, an antigen binds to B-cell receptors (BCRs) (Figure 22.18). These integral transmembrane proteins are chemically similar to the antibodies that eventually are secreted by plasma cells. Although B cells can respond to an unprocessed antigen present in lymph or interstitial fluid, their response is much more intense when they process the antigen. Antigen processing in a B cell occurs in the following way: The antigen is taken into the B cell, broken down into peptide fragments and combined with MHC-II self-antigens, and moved to the B cell plasma membrane. Helper T cells recognize the antigen–MHC-II complex and deliver the costimulation needed for B cell proliferation and differentiation. The helper T cell produces interleukin-2 and other cytokines that function as costimulators to activate B cells.

Once activated, a B cell undergoes clonal selection (Figure 22.18). The result is the formation of a clone of B cells that consists of plasma cells and memory B cells. Plasma cells secrete antibodies. A few days after exposure to an antigen, a plasma cell secretes hundreds of millions of antibodies each day for about 4 or 5 days, until the plasma cell dies. Most antibodies travel in lymph and blood to the invasion site. Interleukin-4 and interleukin-6, also produced by helper T cells, enhance B cell proliferation, B cell differentiation into plasma cells, and secretion of antibodies by plasma cells. Memory B cells do not secrete antibodies. Instead, they can quickly proliferate and differentiate into more plasma cells and more memory B cells should the same antigen reappear at a future time.

Different antigens stimulate different B cells to develop into plasma cells and their accompanying memory B cells. All of the B cells of a particular clone are capable of secreting only one type of antibody, which is identical to the antigen receptor displayed by the B cell that first responded. Each specific antigen

**CHECKPOINT**

16. What are the functions of helper, cytotoxic, and memory T cells?
17. How do cytotoxic T cells kill infected target cells?
18. How is immunological surveillance useful?
activates only those B cells that are predestined (by the combination of gene segments they carry) to secrete antibody specific to that antigen. Antibodies produced by a clone of plasma cells enter the circulation and form antigen–antibody complexes with the antigen that initiated their production.

Antibodies

An antibody (Ab) can combine specifically with the epitope on the antigen that triggered its production. The antibody's structure matches its antigen much as a lock accepts a specific key. In theory, plasma cells could secrete as many different antibodies as there are different B-cell receptors because the same recombined gene segments code for both the BCR and the antibodies eventually secreted by plasma cells.

Antibody Structure

Antibodies belong to a group of glycoproteins called globulins, and for this reason they are also known as immunoglobulins (Igs). Most antibodies contain four polypeptide chains (Figure 22.19). Two of the chains are identical to each other and are called heavy (H) chains; each consists of about 450 amino acids. Short carbohydrate chains are attached to each heavy polypeptide chain. The two other polypeptide chains, also identical to each other, are called light (L) chains, and each consists of about 220 amino acids. A disulfide bond (S—S) holds each light chain to a heavy chain. Two disulfide bonds also link the midregion of the two heavy chains; this part of the antibody displays considerable flexibility and is called the

Figure 22.18 Activation and clonal selection of B cells. Plasma cells are actually much larger than B cells.

Plasma cells secrete antibodies.
Because the antibody “arms” can move somewhat as the hinge region bends, an antibody can assume either a T shape (Figure 22.19a) or a Y shape (Figure 22.19b). Beyond the hinge region, parts of the two heavy chains form the stem region.

Within each H and L chain are two distinct regions. The tips of the H and L chains, called the variable (V) regions, constitute the antigen-binding site. The variable region, which is different for each kind of antibody, is the part of the antibody that recognizes and attaches specifically to a particular antigen. Because most antibodies have two antigen-binding sites, they are said to be bivalent. Flexibility at the hinge allows the antibody to simultaneously bind to two epitopes that are some distance apart—for example, on the surface of a microbe.

The remainder of each H and L chain, called the constant (C) region, is nearly the same in all antibodies of the same class and is responsible for the type of antigen—antibody reaction that occurs. However, the constant region of the H chain differs from one class of antibody to another, and its structure serves as a basis for distinguishing five different classes, designated IgG, IgA, IgM, IgD, and IgE. Each class has a distinct chemical structure and a specific biological role. Because they appear first and are relatively short-lived, IgM antibodies indicate a recent invasion. In a sick patient, the responsible pathogen may be suggested by the presence of high levels of IgM specific to a particular organism. Resistance of the fetus and newborn baby to infection stems mainly from maternal IgG antibodies that cross the placenta before birth and IgA antibodies in breast milk after birth. Table 22.3 summarizes the structures and functions of the five classes of antibodies.

What is the function of the variable regions in an antibody molecule?

**Antibody Actions**

The actions of the five classes of immunoglobulins differ somewhat, but all of them act to disable antigens in some way. Actions of antibodies include:

- **Neutralizing antigen.** The reaction of antibody with antigen blocks or neutralizes some bacterial toxins and prevents attachment of some viruses to body cells.
- **Immobilizing bacteria.** If antibodies form against antigens on the cilia or flagella of motile bacteria, the antigen–antibody reaction may cause the bacteria to lose their motility, which limits their spread into nearby tissues.
- **Agglutinating and precipitating antigen.** Because antibodies have two or more sites for binding to antigen, the antigen–antibody reaction may cross-link pathogens to one another, causing agglutination (clumping together). Phagocytic cells ingest agglutinated microbes more readily. Likewise, soluble antigens may come out of solution and form a more-easily phagocytized precipitate when cross-linked by antibodies.
- **Activating complement.** Antigen–antibody complexes initiate the classical pathway of the complement system (discussed shortly).
- **Enhancing phagocytosis.** The stem region of an antibody acts as a flag that attracts phagocytes once antigens have bound to the antibody’s variable region. Antibodies enhance the activity of phagocytes by causing agglutination and precipitation, by activating complement, and by coating microbes so that they are more susceptible to phagocytosis.
Role of the Complement System in Immunity

The complement system is a defensive system made up of over 30 proteins produced by the liver and found circulating in blood plasma and within tissues throughout the body. Collectively, the complement proteins destroy microbes by causing phagocytosis, neutralization, and triggering the complement system. It is the only class of antibody to cross the placenta from mother to fetus, conferring considerable immune protection in newborns.

Most complement proteins are designated by an uppercase letter $C$, numbered $C_1$ through $C_9$, named for the order in which they were discovered. The $C_1$–$C_9$ complement proteins are inactive and become activated only when split by enzymes into active fragments, which are indicated by lowercase letters $a$ and $b$. For example, inactive complement protein $C_3$ is split into the activated fragments, $C_3a$ and $C_3b$. The active fragments carry out the destructive actions of the $C_1$–$C_9$ complement proteins. Other complement proteins are referred to as factors B, D, and P (properdin).

Complement proteins act in a cascade—one reaction triggers another reaction, which in turn triggers another reaction, and so on. With each succeeding reaction, more and more product is formed so that the net effect is amplified many times.
Complement activation may begin by three different pathways (described shortly), all of which activate C3. Once activated, C3 begins a cascade of reactions that brings about phagocytosis, cytolysis, and inflammation as follows (Figure 22.20):

1. Inactivated C3 splits into activated C3a and C3b.
2. C3b binds to the surface of a microbe and receptors on phagocytes attach to the C3b. Thus C3b enhances phagocytosis by coating a microbe, a process called opsonization (op-so-ni-ZA-shun). Opsonization promotes attachment of a phagocyte to a microbe.
3. C3b also initiates a series of reactions that bring about cytolysis. First, C3b splits C5. The C5b fragment then binds to C6 and C7, which attach to the plasma membrane of an invading microbe. Then C8 and several C9 molecules join the other complement proteins and together form a cylinder-shaped membrane attack complex, which inserts into the plasma membrane.
4. The membrane attack complex creates channels in the plasma membrane that result in cytolysis, the bursting of the microbial cells due to the inflow of extracellular fluid through the channels.
5. C3a and C5a bind to mast cells and cause them to release histamine that increases blood vessel permeability during inflammation. C5a also attracts phagocytes to the site of inflammation (chemotaxis).

Figure 22.20 Complement activation and results of activation. (Adapted from Tortora, Funke, and Case, Microbiology: An Introduction, Eighth Edition, Figure 16.10, Pearson Benjamin-Cummings, 2004.)

When activated, complement proteins enhance phagocytosis, cytolysis, and inflammation.

Which pathway for activation of complement involves antibodies? Explain why.
C3 can be activated in three ways: (1) The **classical pathway** starts when antibodies bind to antigens (microbes). The antigen–antibody complex binds and activates C1. Eventually, C3 is activated and the C3 fragments initiate phagocytosis, cytolysis, and inflammation. (2) The **alternative pathway** does not involve antibodies. It is initiated by an interaction between lipid–carbohydrate complexes on the surface of microbes and complement protein factors B, D, and P. This interaction activates C3. (3) In the **lectin pathway**, macrophages that digest microbes release chemicals that cause the liver to produce proteins called **lectins**. Lectins bind to the carbohydrates on the surface of microbes, ultimately causing the activation of C3.

Once complement is activated, proteins in blood and on body cells such as blood cells break down activated C3. In this way, its destructive capabilities cease very quickly so that damage to body cells is minimized.

**Immunological Memory**

A hallmark of immune responses is memory for specific antigens that have triggered immune responses in the past. Immunological memory is due to the presence of long-lasting antibodies and very long-lived lymphocytes that arise during clonal selection of antigen-stimulated B cells and T cells.

Immune responses, whether cell-mediated or antibody-mediated, are much quicker and more intense after a second or subsequent exposure to an antigen than after the first exposure. Initially, only a few cells have the correct specificity to respond, and the immune response may take several days to build to maximum intensity. Because thousands of memory cells exist after an initial encounter with an antigen, the next time the same antigen appears they can proliferate and differentiate into helper T cells, cytotoxic T cells, or plasma cells within hours.

One measure of immunological memory is **antibody titer** (Titer), the amount of antibody in serum. After an initial contact with an antigen, no antibodies are present for a period of several days. Then, a slow rise in the antibody titer occurs, first IgM and then IgG, followed by a gradual decline in antibody titer (Figure 22.21). This is the **primary response**.

Memory cells may remain for decades. Every new encounter with the same antigen results in a rapid proliferation of memory cells. After subsequent encounters, the antibody titer is far greater than during a primary response and consists mainly of IgG antibodies. This accelerated, more intense response is called the **secondary response**. Antibodies produced during a secondary response have an even higher affinity for the antigen than those produced during a primary response, and thus they are more successful in disposing of it.

Primary and secondary responses occur during microbial infection. When you recover from an infection without taking antimicrobial drugs, it is usually because of the primary response. If the same microbe infects you later, the secondary response could be so swift that the microbes are destroyed before you exhibit any signs or symptoms of infection.

### Figure 22.21 Production of antibodies in the primary (after first exposure) and secondary (after second exposure) responses to a given antigen.

Immunological memory is the basis for successful immunization by vaccination.

![Figure 22.21](image)

**According to this graph, how much more IgG is circulating in the blood in the secondary response than in the primary response? (Hint: Notice that each mark on the antibody titer axis represents a 10-fold increase.)**

Immunological memory provides the basis for immunization by vaccination against certain diseases (for example, polio). When you receive the vaccine, which may contain **attenuated** (weakened) or killed whole microbes or portions of microbes, your B cells and T cells are activated. Should you subsequently encounter the living pathogen as an infecting microbe, your body initiates a secondary response.

To function properly, your T cells must have two traits: (1) They must be able to recognize your own major histocompatibility complex (MHC) proteins, a process known as self-recognition, and (2) they must lack reactivity to peptide fragments from your own proteins, a condition known as self-tolerance (Figure 22.22). B cells also display self-tolerance. Loss of self-tolerance leads to the development of autoimmune diseases (see page 868).

Pre-T cells in the thymus develop the capability for self-recognition via positive selection (Figure 22.22a). In this process, some pre-T cells express T-cell receptors (TCRs) that interact with self-MHC proteins on epithelial cells in the thymic cortex. Because of this interaction, the T cells can recognize the MHC part of an antigen–MHC complex. These T cells survive. Other immature T cells that fail to interact with thymic epithelial cells are not able to recognize self-MHC proteins. These cells undergo apoptosis.

The development of self-tolerance occurs by a weeding-out process called negative selection in which the T cells interact...
with dendritic cells located at the junction of the cortex and medulla in the thymus. In this process, T cells with receptors that recognize self-peptide fragments or other self-antigens are eliminated or inactivated (Figure 22.22a). The T cells selected to survive do not respond to self-antigens, the fragments of molecules that are normally present in the body. Negative selection occurs via both deletion and anergy. In deletion, self-reactive T cells undergo apoptosis and die; in anergy they remain alive but are unresponsive to antigenic stimulation. Only 1–5% of the immature T cells in the thymus receive the proper signals to survive apoptosis during both positive and negative selection and emerge as mature, immunocompetent T cells.

Once T cells have emerged from the thymus, they may still encounter an unfamiliar self-protein; in such cases they may also become anergic if there is no costimulator (Figure 22.22b). Deletion of self-reactive T cells may also occur after they leave the thymus.

B cells also develop tolerance through deletion and anergy (Figure 22.22c). While B cells are developing in bone marrow, those cells exhibiting antigen receptors that recognize common self-antigens (such as MHC proteins or blood group antigens) are deleted. Once B cells are released into the blood, however, anergy appears to be the main mechanism for preventing responses to self-proteins. When B cells encounter an antigen not associated with an antigen-presenting cell, the necessary costimulation signal often is missing. In this case, the B cell is likely to become anergic (inactivated) rather than activated.

Table 22.5 summarizes the activities of cells involved in immune responses.

**STRESS AND IMMUNITY**

**OBJECTIVE**
- Describe the effects of stress on immunity.

The field of psychoneuroimmunology (PNI) deals with communication pathways that link the nervous, endocrine, and immune systems. PNI research appears to justify what people have long observed: Your thoughts, feelings, moods, and beliefs influence your level of health and the course of disease. For example, cortisol, a hormone secreted by the adrenal cortex in association with the stress response, inhibits immune system activity.

If you want to observe the relationship between lifestyle and immune function, visit a college campus. As the semester progresses and the workload accumulates, an increasing number of students can be found in the waiting rooms of student health services. When work and stress pile up, health habits can change. Many people smoke or consume more alcohol when stressed, two habits detrimental to optimal immune function. Under stress, people are less likely to eat well or exercise regularly, two habits that enhance immunity.

People resistant to the negative health effects of stress are more likely to experience a sense of control over the future, a commitment to their work, expectations of generally positive outcomes for themselves, and feelings of social support. To increase your stress resistance, cultivate an optimistic outlook, get involved in your work, and build good relationships with others.

Adequate sleep and relaxation are especially important for a healthy immune system. But when there aren’t enough hours in the day, you may be tempted to steal some from the night. While skipping sleep may give you a few more hours of productive time in the short run, in the long run you end up even farther behind, especially if getting sick keeps you out of commission for several days, blurs your concentration, and blocks your creativity.

Even if you make time to get eight hours of sleep, stress can cause insomnia. If you find yourself tossing and turning at night, it’s time to improve your stress management and relaxation skills! Be sure to unwind from the day before going to bed.

**CHECKPOINT**
23. What do positive selection, negative selection, and anergy accomplish?

**CHECKPOINT**
24. Have you ever observed a connection between stress and illness in your own life?

**AGING AND THE IMMUNE SYSTEM**

**OBJECTIVE**
- Describe the effects of aging on the immune system.

With advancing age, most people become more susceptible to all types of infections and malignancies. Their response to vaccines is decreased, and they tend to produce more autoantibodies (antibodies against their body’s own molecules). In addition, the immune system exhibits lowered levels of function. For example, T cells become less responsive to antigens, and fewer T cells respond to infections. This may result from age-related atrophy of the thymus or decreased production of thymic hormones. Because the T cell population decreases with age, B cells are also less responsive. Consequently, antibody levels do not increase as rapidly in response to a challenge by an antigen, resulting in increased susceptibility to various infections. It is for this key reason that elderly individuals are encouraged to get influenza (flu) vaccinations each year.

**CHECKPOINT**
25. How are T cells affected by aging?
**Focus on Homeostasis**

**AIDS: Acquired Immunodeficiency Syndrome**

Acquired immunodeficiency syndrome (AIDS) is a condition in which a person experiences a telltale assortment of infections due to the progressive destruction of immune system cells by the human immunodeficiency virus (HIV). AIDS represents the end stage of infection by HIV. A person who is infected with HIV may be symptom-free for many years, even while the virus is actively attacking the immune system. In the two decades after the first five cases were reported in 1981, 22 million people died of AIDS. Worldwide, 35 to 40 million people are currently infected with HIV.

**HIV Transmission**

Because HIV is present in the blood and some body fluids, it is most effectively transmitted (spread from one person to another) by actions or practices that involve the exchange of blood or body fluids between people. HIV is transmitted in semen or vaginal fluid during unprotected (without a condom) anal, vaginal, or oral sex. HIV also is transmitted by direct blood-to-blood contact, such as occurs among intravenous drug users who share hypodermic needles or health-care professionals who may be accidentally stuck by HIV-contaminated hypodermic needles. In addition, HIV can be transmitted from an HIV-infected mother to her baby at birth or during breast-feeding.

The chance of transmitting or of being infected by HIV during vaginal or anal intercourse can be greatly reduced—although not entirely eliminated—by the use of latex condoms. Public health programs aimed at encouraging drug users not to share needles have proven effective at checking the increase in new HIV infections in this population. Also, giving certain drugs to pregnant HIV-infected women greatly reduces the risk of transmission of the virus to their babies.

HIV is a very fragile virus; it cannot survive for long outside the human body. The virus is not transmitted by insect bites. One cannot become infected by casual physical contact with an HIV-infected person, such as by hugging or sharing household items. The virus can be eliminated from personal care items and medical equipment by exposing them to heat (135°F for 10 minutes) or by cleaning them with common disinfectants such as hydrogen peroxide, rubbing alcohol, household bleach, or germicidal cleansers such as Betadine or Hibiclens. Standard dishwashing and clothes washing also kill HIV.

**HIV: Structure and Infection**

HIV consists of an inner core of ribonucleic acid (RNA) covered by a protein coat (capsid). HIV is classified as a retrovirus since its genetic information is carried in RNA instead of DNA. Surrounding the HIV capsid is an envelope composed of a lipid bilayer that is penetrated by glycoproteins (Figure 22.23).

Outside a living host cell, a virus is unable to replicate. However, when a virus infects and enters a host cell, it uses the host cell's enzymes and ribosomes to make thousands of copies of the virus. New viruses eventually leave and then infect other cells. HIV infection of a host cell begins with the binding of HIV glycoproteins to receptors in the host cell's plasma membrane. This causes the cell to transport the virus into its cytoplasm via receptor-mediated endocytosis. Once inside the host cell, HIV sheds its protein coat, and a viral enzyme called reverse transcriptase reads the viral RNA strand and makes a DNA copy. The viral DNA copy then becomes integrated into the host cell's DNA. Thus, the viral DNA is duplicated along with the host cell's DNA during normal cell division. In addition, the viral DNA can cause the infected cell to begin producing millions of copies of viral RNA and to assemble new protein coats for each copy. The new HIV copies bud off from the cell's plasma membrane and circulate in the blood to infect other cells.

**Figure 22.23 Human immunodeficiency virus (HIV), the causative agent of AIDS.**

HIV is most effectively transmitted by practices that involve the exchange of body fluids.

**Which cells of the immune system are attacked by HIV?**

HIV mainly damages helper T cells, and it does so in various ways. Over 10 billion viral copies may be produced each day. The viruses bud so rapidly from an infected cell's plasma membrane that cell lysis eventually occurs. In addition, the body's defenses attack the infected cells, killing them but not all the viruses they harbor. In most HIV-infected individuals, helper T cells are initially replaced as fast as they are destroyed. After several years, however, the body's ability to replace helper T cells is slowly exhausted, and the number of helper T cells in circulation progressively declines.

**Signs, Symptoms, and Diagnosis of HIV Infection**

Soon after being infected with HIV, most people experience a brief flu-like illness. Common signs and symptoms are fever, fatigue, rash, headache, joint pain, sore throat, and swollen lymph nodes. About 50% of infected people also experience night sweats. As early as three to four weeks after HIV infection, plasma cells begin secreting antibodies against HIV. These antibodies are detectable in blood plasma and form the basis for some of the screening tests for HIV. When people test “HIV-positive,” it usually means they have antibodies to HIV antigens in their bloodstream.

**Progression to AIDS**

After a period of 2 to 10 years, HIV destroys enough helper T cells that most infected people begin to experience symptoms of immunodeficiency. HIV-infected people commonly have enlarged lymph nodes and experience persistent fatigue, involuntary weight loss, night sweats, skin rashes, diarrhea, and various lesions of the mouth and gums. In addition, the virus may begin to infect neurons in the brain, affecting the person's memory and producing visual disturbances.

As the immune system slowly collapses, an HIV-infected person becomes susceptible to a host of opportunistic infections. These are diseases caused by microorganisms that are normally held in check but now proliferate because of the defective immune system. AIDS is diagnosed when the helper T cell count drops below 200 cells per
microliter (= cubic millimeter) of blood or when opportunistic infections arise, whichever occurs first. In time, opportunistic infections usually are the cause of death.

Treatment of HIV Infection
At present, infection with HIV cannot be cured. Vaccines designed to block new HIV infections and to reduce the viral load (the number of copies of HIV RNA in a microliter of blood plasma) in those who are already infected are in clinical trials. Meanwhile, two categories of drugs have proved successful in extending the life of many HIV-infected people:

1. **Reverse transcriptase inhibitors** interfere with the action of the reverse transcriptase enzyme, the enzyme that the virus uses to convert its RNA into a DNA copy. Among the drugs in this category are zidovudine (ZDV, previously called AZT), didanosine (ddI), and stavudine (d4T®). Trizivir, approved in 2000 for treatment of HIV infection, combines three reverse transcriptase inhibitors in one pill.

2. **Protease inhibitors** interfere with the action of protease, a viral enzyme that cuts proteins into pieces to assemble the protein coat of newly produced HIV particles. Drugs in this category include nelfinavir, saquinavir, ritonavir, and indinavir.

In 1996, physicians treating HIV-infected patients widely adopted **highly active antiretroviral therapy** (HAART)—a combination of two differently acting reverse transcriptase inhibitors and one protease inhibitor. Most HIV-infected individuals receiving HAART experience a drastic reduction in viral load and an increase in the number of helper T cells in their blood. Not only does HAART delay the progression of HIV infection to AIDS, but many individuals with AIDS have seen the remission or disappearance of opportunistic infections and an apparent return to health. Unfortunately, HAART is very costly (exceeding $10,000 per year), the dosing schedule is grueling, and not all people can tolerate the toxic side effects of these drugs. Although HIV may virtually disappear from the blood with drug treatment (and thus a blood test may be “negative” for HIV), the virus typically still lurks in various lymphatic tissues. In such cases, the infected person can still transmit the virus to another person.

**Allergic Reactions**
A person who is overly reactive to a substance that is tolerated by most other people is said to be **allergic** or hypersensitive. Whenever an allergic reaction takes place, some tissue injury occurs. The antigens that induce an allergic reaction are called **allergens**. Common allergens include certain foods (milk, peanuts, shellfish, eggs), antibiotics (penicillin, tetracycline), vaccines (pertussis, typhoid), venoms (honeybee, wasp, snake), cosmetics, chemicals in plants such as poison ivy, pollens, dust, molds, iodine-containing dyes used in certain x-ray procedures, and even microbes.

There are four basic types of hypersensitivity reactions: type I (anaphylactic), type II (cytotoxic), type III (immune-complex), and type IV (cell-mediated). The first three are antibody-mediated immune responses; the last is a cell-mediated immune response.

**Type I (anaphylactic) reactions** are the most common and occur within a few minutes after a person sensitized to an allergen is reexposed to it. In response to the first exposure to certain allergens, some people produce IgE antibodies that bind to the surface of mast cells and basophils. The next time the same allergen enters the body, it attaches to the IgE antibodies already present. In response, the mast cells and basophils release histamine, prostaglandins, leukotrienes, and kinins. Collectively, these mediators cause vasodilation, increased blood capillary permeability, increased smooth muscle contraction in the airways of the lungs, and increased mucus secretion. As a result, a person may experience inflammatory responses, difficulty in breathing through the constricted airways, and a runny nose from excess mucus secretion. In **anaphylactic shock**, which may occur in a susceptible individual who has just received a triggering drug or been stung by a wasp, wheezing and shortness of breath as airways constrict are usually accompanied by shock due to vasodilation and fluid loss from blood. This life-threatening emergency is usually treated by injecting epinephrine to dilate the airways and strengthen the heartbeat.

**Type II (cytotoxic) reactions** are caused by antibodies (IgG or IgM) directed against antigens on a person's blood cells (red blood cells, lymphocytes, or platelets) or tissue cells. The reaction of antibodies and antigens usually leads to activation of complement. Type II reactions, which may occur in incompatible blood transfusion reactions, damage cells by causing lysis.

**Type III (immune-complex) reactions** involve antigens, antibodies (IgA or IgM), and complement. When certain ratios of antigen to antibody occur, the immune complexes are small enough to escape phagocytosis, but they become trapped in the basement membrane under the endothelium of blood vessels, where they activate complement and cause inflammation. Glomerulonephritis and rheumatoid arthritis (RA) arise in this way.

**Type IV (cell-mediated) reactions** or delayed hypersensitivity reactions usually appear 12-72 hours after exposure to an allergen. Type IV reactions occur when allergens are taken up by antigen-presenting cells (such as Langerhans cells in the skin) that migrate to lymph nodes and present the allergen to T cells, which then proliferate. Some of the new T cells return to the site of allergen entry into the body, where they produce gamma-interferon, which activates macrophages, and tumor necrosis factor, which stimulates an inflammatory response. Intracellular bacteria such as *Mycobacterium tuberculosis* trigger this type of cell-mediated immune response, as do certain haptenes, such as poison ivy toxin. The skin test for tuberculosis also is a delayed hypersensitivity reaction.

**Autoimmune Diseases**
In an **autoimmune disease** (aw-tô-î-MUN) or autoimmunity, the immune system fails to display self-tolerance and attacks the person's own tissues. Autoimmune diseases usually arise in early adulthood and are common, afflicting an estimated 5% of adults in North America and Europe. Females suffer autoimmune diseases twice as often as males. Recall that self-reactive B cells and T cells normally are deleted or undergo anergy during negative selection (see Figure 22.22). Apparently, this process is not 100% effective. Under the influence of unknown environmental triggers and certain genes that make some people more susceptible, self-tolerance breaks down, leading to activation of self-reactive clones of T cells and B cells. These cells then generate cell-mediated or antibody-mediated immune responses against self-antigens.

A variety of mechanisms produce different autoimmune diseases. Some involve production of **autoantibodies**, antibodies that bind to and stimulate or block self-antigens. For example, autoantibodies that mimic TSH (thyroid-stimulating hormone) are present in Graves disease and stimulate secretion of thyroid hormones (thus producing hyperthyroidism); autoantibodies that bind to and block acetylcholine receptors cause the muscle weakness characteristic of myasthenia gravis. Other autoimmune diseases involve activation of cytotoxic T cells that destroy certain body cells. Examples include type 1 diabetes mellitus, in which T cells attack the insulin-producing pancreatic beta cells, and multiple sclerosis (MS), in which T cells attack myelin...
Infectious Mononucleosis

Infectious mononucleosis or “mono” is a contagious disease caused by the Epstein-Barr virus (EBV). It occurs mainly in children and young adults, and more often in females than in males. The virus most commonly enters the body through intimate oral contact such as kissing, which accounts for its common name, the “kissing disease.” EBV then multiplies in lymphatic tissues and filters into the blood, where it infects and multiplies in B cells, the primary host cells. Because of this infection, the B cells become so enlarged and abnormal in appearance that they resemble monocytes, the primary reason for the term mononucleosis. In addition to an elevated white blood cell count with an abnormally high percentage of lymphocytes, signs and symptoms include fatigue, headache, dizziness, sore throat, enlarged and tender lymph nodes, and fever. There is no cure for infectious mononucleosis, but the disease usually runs its course in a few weeks.

Lymphomas

Lymphomas (lim-FÖ-mas; lymph = clear water; -oma = tumor) are cancers of the lymphatic organs, especially the lymph nodes. Most have no known cause. The two main types of lymphomas are Hodgkin disease and non-Hodgkin lymphoma.

Hodgkin disease (HD) is characterized by a painless, nontender enlargement of one or more lymph nodes, most commonly in the neck, chest, and axilla. If the disease has metastasized from these sites, fever, night sweats, weight loss, and bone pain also occur. HD primarily affects individuals between ages 15 and 35 and those over 60, and it is more common in males. If diagnosed early, HD has a 90–95% cure rate.

Non-Hodgkin lymphoma (NHL), which is more common than HD, occurs in all age groups, the incidence increasing with age to a maximum between ages 45 and 70. NHL may start the same way as HD but may also include an enlarged spleen, anemia, and general malaise. Up to half of all individuals with NHL are cured or survive for a lengthy period. Treatment options for both HD and NHL include radiation therapy, chemotherapy, and bone marrow transplantation.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (er-ē-thém-a-TÖ-sus), SLE, or simply lupus (lupus = wolf) is a chronic autoimmune, inflammatory disease that affects multiple body systems. Lupus is characterized by periods of active disease and remission; symptoms range from mild to life-threatening. Lupus most often develops between ages 15 and 44 and is 10–15 times more common in females than males. It is also 2–3 times more common in African-Americans, Hispanics, Asian-Americans, and Native Americans than in European-Americans. Although the cause of SLE is not known, both a genetic predisposition to the disease and environmental factors (infections, antibiotics, ultraviolet light, stress, and hormones) may trigger it. Sex hormones appear to influence the development of SLE. The disorder often occurs in females who exhibit extremely low levels of androgens.

Signs and symptoms of SLE include joint pain, muscle pain, chest pain with deep breaths, headaches, pale or purple fingers or toes, kidney dysfunction, low blood cell count, nerve or brain dysfunction, slight fever, fatigue, oral ulcers, weight loss, swelling in the legs or around the eyes, enlarged lymph nodes and spleen, photosensitivity, rapid loss of large amounts of scalp hair, and sometimes an eruption across the bridge of the nose and cheeks called a “butterfly rash.” The erosive nature of some of the SLE skin lesions was thought to resemble the damage inflicted by the bite of a wolf—thus, the term lupus.

Two immunological features of SLE are excessive activation of B cells and inappropriate production of autoantibodies against DNA (anti-DNA antibodies) and other components of cellular nuclei such as histone proteins. Triggers of B cell activation are thought to include various chemicals and drugs, viral and bacterial antigens, and exposure to sunlight. Circulating complexes of abnormal autoantibodies and their “antigens” cause damage in tissues throughout the body. Kidney damage occurs as the complexes become trapped in the basement membrane of kidney capillaries, obstructing blood filtering. Renal failure is the most common cause of death.

There is no cure for lupus, but drug therapy can minimize symptoms, reduce inflammation, and forestall flare-ups. The most commonly used lupus medications are pain relievers (nonsteroidal anti-inflammatory drugs such as aspirin and ibuprofen), antimalarial drugs (hydroxychloroquine), and corticosteroids (prednisone and hydrocortisone).

**MEDICAL TERMINOLOGY**

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adenitis (ad-e-NÍ-tis)</td>
<td>Inflammation of a gland. Inflammation of lymph nodes resulting from an infection.</td>
</tr>
<tr>
<td>Allograft (AL-Ò-graff)</td>
<td>A transplant between genetically distinct individuals of the same species. Skin transplants from other people and blood transfusions are allografts.</td>
</tr>
<tr>
<td>Autograft (AW-TÒ-graff)</td>
<td>A transplant in which one's own tissue is grafted to another part of the body (such as skin grafts for burn treatment or plastic surgery).</td>
</tr>
<tr>
<td>Chronic fatigue syndrome (CFS)</td>
<td>A disorder, usually occurring in young adults and primarily in females, characterized by (1) extreme fatigue that impairs normal activities for at least 6 months and (2) the absence of other known diseases (cancer, infections, drug abuse, toxicity, or psychiatric disorders) that might produce similar symptoms.</td>
</tr>
<tr>
<td>Gamma globulin (GLOB-u¯-lin) Suspension of immunoglobulins from blood consisting of antibodies that react with a specific pathogen. It is prepared by injecting the pathogen into animals, removing blood from the animals after antibodies have been produced, isolating the antibodies, and injecting them into a human to provide short-term immunity.</td>
<td></td>
</tr>
<tr>
<td>Hypersplenism (hi-per-SPLÈN-izm; hyper- = over) Abnormal splenic activity due to splenic enlargement and associated with an increased rate of destruction of normal blood cells.</td>
<td></td>
</tr>
</tbody>
</table>
Lymphadenopathy (lim-fa’d-e-NOP-a-the; lymph- = clear fluid; -pathy = disease) Enlarged, sometimes tender lymph glands as a response to infection; also called swollen glands.

Lymphangitis (lim-fan-JI¯-tis; -itis = inflammation of) Inflammation of lymphatic vessels.

Lymphedema (lim ‘fe-DÉ-ma; edema = swelling) Accumulation of lymph in lymphatic vessels, causing painless swelling of a limb.

Severe combined immunodeficiency disease (SCID) A rare inherited disorder in which both B cells and T cells are missing or inactive. Scientists have now identified mutations in several genes that are responsible for some types of SCID. In some cases, an infusion of red bone marrow cells from a sibling having very similar MHC (HLA) antigens can provide normal stem cells that give rise to normal B and T cells. The result can be a complete cure. Less than 30% of afflicted patients, however, have a compatible sibling who could serve as a donor.

Splenomegaly (splé ‘nö-MEG-a-lë; mega- = large) Enlarged spleen.

Tonsillectomy (ton’-si-LEK-tô-më; -ectomy = excision) Removal of a tonsil.

Xenograft (zen-ô-graff; xeno- = strange or foreign) A transplant between animals of different species. Xenografts from porcine (pig) or bovine (cow) tissue may be used in humans as a physiological dressing for severe burns. Other xenografts include pig heart valves and baboon hearts.

STUDY OUTLINE

Introduction (p. 831)

1. The ability to ward off disease is called immunity (resistance). Lack of resistance is called susceptibility.
2. The two general types of immunity are (a) innate and (b) adaptive.
3. Innate immunity refers to a wide variety of body responses to a wide range of pathogens.
4. Adaptive immunity involves activation of specific lymphocytes to combat a particular foreign substance.

Lymphatic System Structure and Function (p. 832)

1. The lymphatic system carries out immune responses and consists of lymph, lymphatic vessels, and structures and organs that contain lymphatic tissue (specialized reticular tissue containing many lymphocytes).
2. The lymphatic system drains interstitial fluid, transports dietary lipids, and protects against invasion through immune responses.
3. Lymphatic vessels begin as closed-ended lymphatic capillaries in tissue spaces between cells.
4. Interstitial fluid drains into lymphatic capillaries, thus forming lymph.
5. Lymph capillaries merge to form larger vessels, called lymphatic vessels, which convey lymph into and out of lymph nodes.
6. The route of lymph flow is from lymph capillaries to lymphatic vessels to lymph trunks to the thoracic duct (left lymphatic duct) and right lymphatic duct to the subclavian veins.
7. Lymph flows because of skeletal muscle contractions and respiratory movements. Valves in lymphatic vessels also aid flow of lymph.
8. The primary lymphatic organs are red bone marrow and the thymus. Secondary lymphatic organs are lymph nodes, the spleen, and lymphatic nodules.
9. The thymus lies between the sternum and the large blood vessels above the heart. It is the site of T cell maturation.
10. Lymph nodes are encapsulated, egg-shaped structures located along lymphatic vessels.
11. Lymph enters lymph nodes through afferent lymphatic vessels, is filtered, and exits through efferent lymphatic vessels.
12. Lymph nodes are the site of proliferation of B cells and T cells.
13. The spleen is the largest single mass of lymphatic tissue in the body. Within the spleen, B cells and T cells carry out immune functions and macrophages destroy blood-borne pathogens and worn-out red blood cells by phagocytosis.
14. Lymphatic nodules are scattered throughout the mucosa of the gastrointestinal, respiratory, urinary, and reproductive tracts. This lymphatic tissue is termed mucosa-associated lymphatic tissue (MALT).

Development of Lymphatic Tissues (p. 841)

1. Lymphatic vessels develop from lymph sacs, which arise from developing veins. Thus, they are derived from mesoderm.
2. Lymph nodes develop from lymph sacs that become invaded by mesenchymal cells.

Innate Immunity (p. 842)

1. Innate immunity includes physical factors, chemical factors, antimicrobial proteins, natural killer cells, phagocytes, inflammation, and fever.
2. The skin and mucous membranes are the first line of defense against entry of pathogens.
3. Antimicrobial substances include interferons, the complement system, iron-binding proteins, and antimicrobial proteins.
4. Natural killer cells and phagocytes attack and kill pathogens and defective cells in the body.
5. Inflammation aids disposal of microbes, toxins, or foreign material at the site of an injury, and prepares the site for tissue repair.
6. Fever intensifies the antiviral effects of interferons, inhibits growth of some microbes, and speeds up body reactions that aid repair.
7. Table 22.1 on page 846 summarizes the innate defenses.

Adaptive Immunity (p. 846)

1. Adaptive immunity involves lymphocytes called B cells and T cells.
2. B cells and T cells arise from stem cells in red bone marrow.
3. B cells mature in red bone marrow, whereas T cells mature in the thymus gland.
4. Before B cells leave the red bone marrow or T cells leave the thymus, they develop immunocompetence, the ability to carry out adaptive immune responses. This process involves the insertion of antigen receptors into their plasma membranes. Antigen receptors are molecules that are capable of recognizing specific antigens.
5. Two major types of mature T cells exit the thymus: helper T cells (also known as CD4 T cells) and cytotoxic T cells (also referred to as CD8 T cells).

6. There are two types of adaptive immunity: cell-mediated immunity and antibody-mediated immunity. In cell-mediated immune responses, cytotoxic T cells directly attack invading antigens; in antibody-mediated immune responses, B cells transform into plasma cells that secrete antibodies.

7. Clonal selection is the process by which a lymphocyte proliferates and differentiates in response to a specific antigen. The result of clonal selection is the formation of a clone of cells that can recognize the same specific antigen as the original lymphocyte.

8. A lymphocyte that undergoes clonal selection gives rise to two major types of cells in the clone: effector cells and memory cells.

9. The effector cells of a lymphocyte clone carry out immune responses that ultimately result in the destruction or inactivation of the antigen. Effector cells include active helper T cells, which are part of a helper T cell clone; active cytotoxic T cells, which are part of a cytotoxic T cell clone; and plasma cells, which are part of a B cell clone.

10. The memory cells of a lymphocyte clone do not actively participate in the initial immune response. However, if the antigen reappears in the body, the memory cells can quickly respond to the antigen by proliferating and differentiating into more effector cells and more memory cells. Memory cells include memory helper T cells, which are part of a helper T cell clone; memory cytotoxic T cells, which are part of a cytotoxic T cell clone; and memory B cells, which are part of a B cell clone.

11. Antigens (Ags) are chemical substances that are recognized as foreign by the immune system.

12. Antigen receptors exhibit great diversity due to genetic recombination.

13. “Self-antigens” called major histocompatibility complex (MHC) antigens are unique to each person’s body cells. All cells except red blood cells display MHC-I molecules. Antigen-presenting cells (APCs) display MHC-II molecules. APCs include macrophages, B cells, and dendritic cells.

14. Exogenous antigens (formed outside body cells) are presented with MHC-II molecules; endogenous antigens (formed inside body cells) are presented with MHC-I molecules.

15. Cytokines are small protein hormones that may stimulate or inhibit many normal cell functions such as growth and differentiation. Other cytokines regulate immune responses (see Table 22.2 on page 852).

Cell-Mediated Immunity (p. 853)

1. A cell-mediated immune response begins with activation of a small number of T cells by a specific antigen.

2. During the activation process, T-cell receptors (TCRs) recognize antigen fragments associated with MHC molecules on the surface of a body cell.

3. Activation of T cells also requires costimulation, either by cytokines such as interleukin-2 or by pairs of plasma membrane molecules.

4. Once a T cell has been activated, it undergoes clonal selection. The result of clonal selection is the formation of a clone of effector cells and memory cells. The effector cells of a T cell clone carry out immune responses that ultimately result in elimination of the antigen.

5. Helper T cells display CD4 protein, recognize antigen fragments associated with MHC-II molecules, and secrete several cytokines, most importantly interleukin-2, which acts as a costimulator for other helper T cells, cytotoxic T cells, and B cells.

6. Cytotoxic T cells display CD8 protein and recognize antigen fragments associated with MHC-I molecules.

7. Active cytotoxic T cells eliminate invaders by (1) releasing granzymes that cause target cell apoptosis (phagocytes then kill the microbes) and (2) releasing perforin, which causes cytolysis, and granulysin that destroys the microbes.

8. Cytotoxic T cells, macrophages, and natural killer cells carry out immunological surveillance, recognizing and destroying cancerous cells that display tumor antigens.

Antibody-Mediated Immunity (p. 856)

1. An antibody-mediated immune response begins with activation of a B cell by a specific antigen.

2. B cells can respond to unprocessed antigens, but their response is more intense when they process the antigen. Interleukin-2 and other cytokines secreted by helper T cells provide costimulation for activation of B cells.

3. Once activated, a B cell undergoes clonal selection, forming a clone of plasma cells and memory cells. Plasma cells are the effector cells of a B cell clone; they secrete antibodies.

4. An antibody (Ab) is a protein that combines specifically with the antigen that triggered its production.

5. Antibodies consist of heavy and light chains and variable and constant regions.

6. Based on chemistry and structure, antibodies are grouped into five principal classes (IgG, IgA, IgM, IgD, and IgE), each with specific biological roles.

7. Actions of antibodies include neutralization of antigen, immobilization of bacteria, agglutination and precipitation of antigen, activation of complement, and enhancement of phagocytosis.

8. Complement is a group of proteins that complement immune responses and help clear antigens from the body.

9. Immunization against certain microbes is possible because memory B cells and memory T cells remain after a primary response to an antigen. The secondary response provides protection should the same microbe enter the body again.

Self-Recognition and Self-Tolerance (p. 862)

1. T cells undergo positive selection to ensure that they can recognize self-MHC proteins (self-recognition), and negative selection to ensure that they do not react to other self-proteins (self-tolerance). Negative selection involves both deletion and anergy.

2. B cells develop tolerance through deletion and anergy.

Stress and Immunity (p. 864)

1. Psychoneuroimmunology (PNI) deals with communication pathways that link the nervous, endocrine, and immune systems. Thoughts, feelings, moods, and beliefs influence health and the course of disease.

2. Under stress, people are less likely to eat well or exercise regularly, two habits that enhance immunity.

Aging and the Immune System (p. 864)

1. With advancing age, individuals become more susceptible to infections and malignancies, respond less well to vaccines, and produce more autoantibodies.

2. Immune responses also diminish with age.
SELF-QUIZ QUESTIONS

1. The first line of defense of innate immunity against pathogens consists of the _____ and _____.: the second line of defense consists of _____, _____, and _____.

2. Substances that are recognized as foreign and provoke immune responses are known as _____.

Indicate whether the following statements are true or false.

3. Your body’s ability to ward off damage or disease through your defenses is known as resistance; vulnerability to disease is susceptibility.

4. Your T cells must be able to recognize your own MHC molecules, a process known as self-recognition, and lack reactivity to peptide fragments from your own proteins, a condition known as self-tolerance.

Choose the one best answer to the following questions.

5. Trace the sequence of fluid from blood vessel to blood vessel by way of the lymphatic system. (1) lymphatic vessels, (2) blood capillaries, (3) subclavian veins, (4) lymphatic capillaries, (5) interstitial spaces, (6) arteries, (7) lymphatic ducts.

(a) 2, 5, 4, 1, 7, 6, 3 (b) 3, 6, 2, 4, 5, 1, 7 (c) 6, 2, 5, 4, 1, 7, 3 (d) 6, 2, 5, 4, 1, 7, 3, 6 (e) 2, 5, 4, 1, 7, 3, 6

6. Which of the following describe lymph nodes? (1) Lymph enters the nodes through efferent lymphatic vessels and leaves through afferent lymphatic vessels. (2) The outer cortex consists of lymphatic nodules that contain B cells and are the sites of plasma cell and memory B cell formation. (3) The inner cortex contains lymphatic nodules with mature T cells. (4) The reticular fibers within the sinuses of the lymph nodes trap foreign substances in the lymph. (5) The sinuses of lymph nodes are known as red pulp.

(a) 1, 2, 3, and 4 (b) 2, 4, and 5 (c) 1, 2, 3, and 4, and 5 (d) 2 and 4 (e) 1, 2, and 4

7. Which of the following statements are correct? (1) Lymphatic vessels are found throughout the body, except in avascular tissues, the CNS, portions of the spleen, and red bone marrow. (2) Lymphatic capillaries allow interstitial fluid to flow into them but not out of them. (3) Anchoring filaments attach lymphatic endothelial cells to surrounding tissues. (4) Lymphatic vessels freely receive all the components of blood, including the formed elements. (5) Lymph ducts directly connect to blood vessels by way of the subclavian veins.

(a) 1, 3, 4, and 5 (b) 2, 3, 4, and 5 (c) 1, 2, 3, and 4 (d) 1, 2, 4, and 5 (e) 1, 2, 3, and 5

8. Which of the following are physical factors that help fight pathogens and disease? (1) numerous layers of the epidermis, (2) mucus of mucous membranes, (3) saliva, (4) interferons, (5) complement.

(a) 1, 3, and 4 (b) 2, 4, and 5 (c) 1, 4, and 5 (d) 1, 2, and 3 (e) 1, 2, and 4

9. Which of the following are functions of antibodies? (1) neutralization of antigens, (2) immobilization of bacteria, (3) agglutination and precipitation of antigens, (4) activation of complement, (5) enhancement of phagocytosis.

(a) 1, 3, and 4 (b) 2, 4, and 5 (c) 1, 2, 3, and 4, and 5 (d) 1, 2, 3, and 5 (e) 1, 2, 3, 4, and 5

10. Which of the following are true? (1) Lymphatic vessels resemble arteries. (2) Lymph is very similar to interstitial fluid. (3) Lacteals are specialized lymphatic capillaries responsible for transporting dietary lipids. (4) Lymph is normally a cloudy, pale yellow fluid. (5) The thoracic duct drains lymph from the upper right side of the body. (6) Lymph flow is maintained by skeletal muscle contractions, one-way valves, and breathing movements.

(a) 1, 2, 5, and 6 (b) 2, 3, and 6 (c) 2, 3, 4, and 6 (d) 2, 4, and 6 (e) 3, 5, and 6

11. Place the stages of phagocytosis in the correct order of occurrence. (1) formation of phagosome, (2) adherence to microbe, (3) destruction of microbe, (4) ingestion to form a phagosome, (5) chemotactic attraction of phagocyte.

(a) 2, 5, 4, 1, 3 (b) 4, 5, 2, 1, 3 (c) 5, 2, 4, 1, 3 (d) 5, 4, 2, 3, 1 (e) 2, 5, 1, 4, 3

12. Place in order the steps involved in cell-mediated immune response to an exogenous antigen.

(a) costimulation and activation of helper T cells (b) presentation of antigen to helper T cells (c) elimination of invaders through the release of granzymes, perforin, granulysin, or lymphotoxin or by attraction and activation of phagocytes (d) proliferation and differentiation of helper T cells to produce a helper T cell clone (e) antigen processing by dendritic cells, macrophages, or B cells (f) recognition of antigen fragments associated with MHC-II molecules by T-cell receptors (g) secretion of cytokines such as interleukin-2 by activated helper T cells (h) migration of antigen-presenting cells to lymphatic tissue (i) activation of cytotoxic T cells

13. Match the following:

(a) encapsulated bean-shaped structures located along the length of lymphatic vessels; contain T and B cells, macrophages, and follicular dendritic cells; filter lymph (b) produces pre-T cells and B cells; found in flat bones and epiphyses of long bones (c) clusters of lymphatic nodules involved in immune responses against inhaled or ingested foreign substances (d) the single largest mass of lymphatic tissue in the body; consists of red and white pulp (e) responsible for the maturation of T cells (f) lymphatic nodules associated with mucous membranes of the digestive, urinary, reproductive, and respiratory systems (g) nonencapsulated clusters of lymphocytes

(a) red bone marrow (2) thymus (3) lymph nodes (4) spleen (5) mucosa-associated lymphatic tissue (6) lymphatic nodules (7) tonsils
14. Match the following:

(a) recognize foreign antigens combined with MHC-1 molecules on the surface of body cells infected by microbes, some tumor cells, and cells of a tissue transplant; display CD8 proteins

(b) are programmed to recognize the reappearance of a previously encountered antigen

(c) differentiate into plasma cells that secrete specific antibodies

(d) process and present exogenous antigens; include macrophages, B cells, and dendritic cells

(e) secrete cytokines as costimulators; display CD4 proteins

(f) ingest microbes or any foreign particulate matter; include neutrophils and macrophages

(g) lymphocytes that have the ability to kill a wide variety of infectious microbes plus certain spontaneously arising tumor cells; lack antigen receptors

15. Match the following (answers may be used more than once):

(a) participate in inflammation, opsonization, and cytolysis

(b) stimulate histamine release, attract neutrophils by chemotaxis, promote phagocytosis, and destroy bacteria

(c) glycoproteins that mark the surface of all body cells except for RBCs; distinguish self from nonself

(d) foreign antigens present in fluids outside body cells

(e) foreign antigens synthesized within a body cell

(f) small protein hormones that stimulate or inhibit many normal cell functions; serve as co-stimulators for B cell and T cell activity

(g) a substance that has reactivity but lacks immunogenicity

(h) causes vasodilation and increased permeability of blood vessels; is found in mast cells in connective tissue and in basophils and platelets in blood

(i) polypeptides formed in blood; induce vasodilation and increased permeability of blood vessels; serve as chemotactic agents for phagocytes

(j) released by damaged cells; intensify the effects of histamine and kinins

(k) small parts of antigens that initiate immune responses

(l) produced by virus-infected cells, they interfere with viral replication in host cells

(m) chemicals released by NK and cytotoxic T cells that can cause apoptosis in target cells

(n) glycoproteins that contain four polypeptide chains, two of which are identical to each other and two of which are variable and contain the antigen-binding site

(o) produced by basophils and mast cells; involved in chemotaxis, adherence, and increased permeability
CRITICAL THINKING QUESTIONS

1. Esperanza watched as her mother got her “flu shot.” “Why do you need a shot if you’re not sick?” she asked. “So I won’t get sick,” answered her mom. Explain how the influenza vaccination prevents illness.

2. Due to the presence of breast cancer, Mrs. Franco had a right radical mastectomy in which her right breast and underlying muscle, right axillary lymph nodes and vessels were removed. Now she is experiencing severe swelling in her right arm. Why did the surgeon remove lymph tissue as well as the breast? Why is Mrs. Franco’s right arm swollen?

3. Tariq’s little sister has the mumps. Tariq can’t remember if he has had mumps or not, but he is feeling slightly feverish. How could Tariq’s doctor determine if he is getting sick with mumps or if he has previously had mumps?

ANSWERS TO FIGURE QUESTIONS

22.1 Red bone marrow contains stem cells that develop into lymphocytes.
22.2 Lymph is more similar to interstitial fluid than to blood plasma because the protein content of lymph is low.
22.3 The left and right lumbar trunks and the intestinal trunk empty into the cisterna chyli, which then drains into the thoracic duct.
22.4 Inhalation promotes the movement of lymph from abdominal lymphatic vessels toward the thoracic region because the pressure in the vessels of the thoracic region is lower than the pressure in the abdominal region when you inhale.
22.5 T cells mature in the thymus.
22.6 Foreign substances in lymph that enter a lymph node may be phagocytized by macrophages or attacked by lymphocytes that mount immune responses.
22.7 White pulp of the spleen functions in immunity; red pulp of the spleen performs functions related to blood cells.
22.8 Lymphatic tissues begin to develop by the end of the fifth week of gestation.
22.9 Lysozyme, digestive enzymes, and oxidants can kill microbes ingested during phagocytosis.
22.10 Redness results from increased blood flow due to vasodilation; pain, from injury of nerve fibers, irritation by microbial toxins, kinins, and prostaglandins; and pressure due to edema; heat, from increased blood flow and heat released by locally increased metabolic reactions; swelling, from leakage of fluid from capillaries due to increased permeability.
22.11 Helper T cells participate in both cell-mediated and antibody-mediated immune responses.
22.12 Epitopes are small immunogenic parts of a larger antigen; haptons are small molecules that become immunogenic only when they attach to a body protein.
22.13 APCs include macrophages in tissues throughout the body, B cells in blood and lymphatic tissue, and dendritic cells in mucous membranes and the skin.
22.14 Endogenous antigens include viral proteins, toxins from intracellular bacteria, and abnormal proteins synthesized by a cancerous cell.
22.15 The first signal in T-cell activation is antigen binding to a TCR; the second signal is a costimulator, such as a cytokine or another pair of plasma membrane molecules.
22.16 The CD8 protein of a cytotoxic T cell binds to the MHC-I molecule of an infected body cell to help anchor the T cell receptor (TCR)—antigen interaction so that antigen recognition can occur.
22.17 Cytotoxic T cells attack some tumor cells and transplanted tissue cells, as well as cells infected by microbes.
22.18 Since all of the plasma cells in this figure are part of the same clone, they secrete just one kind of antibody.
22.19 The variable regions recognize and bind to a specific antigen.
22.20 The classical pathway for the activation of complement is linked to antibody-mediated immunity because Ag–Ab complexes activate C1.
22.21 At peak secretion, approximately 1000 times more IgG is produced in the secondary response than in the primary response.
22.22 In deletion, self-reactive T cells or B cells die; in anergy, T cells or B cells are alive but are unresponsive to antigenic stimulation.
22.23 HIV attacks helper T cells.
THE RESPIRATORY SYSTEM

THE RESPIRATORY SYSTEM AND HOMEOSTASIS
The respiratory system contributes to homeostasis by providing for the exchange of gases—oxygen and carbon dioxide—between the atmospheric air, blood, and tissue cells. It also helps adjust the pH of body fluids.

Your body’s cells continually use oxygen (O₂) for the metabolic reactions that release energy from nutrient molecules and produce ATP. At the same time, these reactions release carbon dioxide (CO₂). Because an excessive amount of CO₂ produces acidity that can be toxic to cells, excess CO₂ must be eliminated quickly and efficiently. The cardiovascular and respiratory systems cooperate to supply O₂ and eliminate CO₂. The respiratory system provides for gas exchange—intake of O₂ and elimination of CO₂—and the cardiovascular system transports blood containing the gases between the lungs and body cells. Failure of either system disrupts homeostasis by causing rapid death of cells from oxygen starvation and buildup of waste products. In addition to functioning in gas exchange, the respiratory system also participates in regulating blood pH, contains receptors for the sense of smell, filters inspired air, produces sounds, and rids the body of some water and heat in exhaled air. Like the digestive and urinary systems that will be covered in subsequent chapters, in the respiratory system there is an extensive area of contact between the external environment and capillary blood vessels. This area of contact allows the body to constantly renew and replenish the internal fluid environment that surrounds and nourishes every body cell.
RESPIRATORY SYSTEM ANATOMY

OBJECTIVES

- Describe the anatomy and histology of the nose, pharynx, larynx, trachea, bronchi, and lungs.
- Identify the functions of each respiratory system structure.

The respiratory system consists of the nose, pharynx (throat), larynx (voice box), trachea (windpipe), bronchi, and lungs (Figure 23.1). Its parts can be classified according to either structure or function. Structurally, the respiratory system consists of two parts: (1) The upper respiratory system includes the nose, pharynx, and associated structures. (2) The lower respiratory system includes the larynx, trachea, bronchi, and lungs. Functionally, the respiratory system also consists of two parts: (1) The conducting zone consists of a series of interconnecting cavities and tubes both outside and within the lungs. These include the nose, pharynx, larynx, trachea, bronchi, bronchioles, and terminal bronchioles; their function is to filter, warm, and moisten air and conduct it into the lungs. (2) The respiratory zone consists of tissues within the lungs where gas exchange occurs. These include the respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli; they are the main sites of gas exchange between air and blood.

The branch of medicine that deals with the diagnosis and treatment of diseases of the ears, nose, and throat (ENT) is called otolaryngology (ō-tō-rī-lār-iŋ-ol-o-jē; oto = ear; rhino = nose; laryngo = voice box; -logy = study of). A pulmonologist is a specialist in the diagnosis and treatment of diseases of the lungs.

Nose

The nose can be divided into external and internal portions. The external nose is the portion of the nose visible on the face and consists of a supporting framework of bone and hyaline cartilage covered with muscle and skin and lined by a mucous membrane. The frontal bone, nasal bones, and maxillae form the bony framework of the external nose (Figure 23.2a on page 877). The cartilaginous framework of the external nose consists of the septal nasal cartilage, which forms the anterior portion of the nasal septum; the lateral nasal cartilages inferior to the nasal bones; and the alar cartilages, which form a portion of the walls of the nostrils. Because it consists of pliable hyaline cartilage, the cartilaginous framework of the external nose is somewhat flexible. On the undersurface of the external nose are two openings called the external nares (NA-rez; singular is naris) or nostrils. Figure 23.3 on page 878 shows the surface anatomy of the nose.

The interior structures of the external nose have three functions: (1) warming, moistening, and filtering incoming air; (2) detecting olfactory stimuli; and (3) modifying speech vibrations as they pass through the large, hollow resonating chambers. Resonance refers to prolonging, amplifying, or modifying a sound by vibration.

The internal nose is a large cavity beyond the nasal vestibule in the anterior aspect of the skull that lies inferior to the nasal bone and superior to the mouth; it is lined with muscle and mucous membrane. Anteriorly, the internal nose merges with the external nose, and posteriorly it communicates with the pharynx through two openings called the internal nares or choanae (kō-Ā-nē) (see Figure 23.2b). Ducts from the paranasal sinuses (which drain mucus) and the nasolacrical ducts (which drain tears) also open into the internal nose. Recall from Chapter 7 that the paranasal sinuses are cavities in certain cranial and facial bones lined with mucous membranes that are continuous with the lining of the nasal cavity. Skull bones containing the paranasal sinuses are the frontal, sphenoid, ethmoid, and maxillae. Besides producing mucus, the paranasal sinuses serve as resonating chambers for sound as we speak or sing. The lateral walls of the internal nose are formed by the ethmoid, maxillae, lacrimal, palatine, and inferior nasal conchae bones (see Figure 7.9 on page 210); the ethmoid bone also forms the roof. The palatine bones and palatine processes of the maxillae, which together constitute the hard palate, form the floor of the internal nose.

The space within the internal nose is called the nasal cavity. The anterior portion of the nasal cavity just inside the nostrils, called the nasal vestibule, is surrounded by cartilage; the superior part of the nasal cavity is surrounded by bone. A vertical partition, the nasal septum, divides the nasal cavity into right and left sides. The anterior portion of the nasal septum consists primarily of hyaline cartilage; the remainder is formed by the vomer, perpendicular plate of the ethmoid, maxillae, and palatine bones (see Figure 7.11 on page 213).

When air enters the nostrils, it passes first through the vestibule, which is lined by skin containing coarse hairs that filter out large dust particles. Three shelves formed by projections of the superior, middle, and inferior nasal conchae extend out of each lateral wall of the nasal cavity. The conchae, almost reaching the nasal septum, subdivide each side of the nasal cavity into a series of groovelike passageways—the superior, middle, and inferior meatuses (mē-Ā-tus-ez = openings or passages; singular is meatus). Mucous membrane lines the cavity and its shelves. The arrangement of conchae and meatuses increases surface area in the internal nose and prevents dehydration by trapping water droplets during exhalation.
Figure 23.1 Structures of the respiratory system.

The upper respiratory system includes the nose, pharynx, and associated structures; the lower respiratory system includes the larynx, trachea, bronchi, and lungs.

Functions

1. Provides for gas exchange—intake of O₂ for delivery to body cells and elimination of CO₂ produced by body cells.
2. Helps regulate blood pH.
3. Contains receptors for the sense of smell, filters inspired air, produces vocal sounds (phonation), and excretes small amounts of water and heat.

Which structures are part of the conducting zone of the respiratory system?
As air passes through the nose, it is warmed, filtered, moistened, and olfaction occurs.

(a) Anterolateral view of external portion of nose showing cartilaginous and bony framework

(b) Sagittal section of the left side of the head and neck showing the location of respiratory structures
The olfactory receptors lie in a region of the membrane lining the superior nasal conchae and adjacent septum called the olfactory epithelium. Inferior to the olfactory epithelium, the mucous membrane contains capillaries and pseudostratified ciliated columnar epithelium with many goblet cells. As inhaled air swirls around the conchae and meatuses, it is warmed by blood in the capillaries. Mucus secreted by the goblet cells moistens the air and traps dust particles. Drainage from the nasolacrimal ducts also helps moisten the air, and is sometimes assisted by secretions from the paranasal sinuses. The cilia move the mucus and trapped dust particles toward the pharynx, at which point they can be swallowed or spit out, thus removing the particles from the respiratory tract.

**CHECKPOINT**
1. What functions do the respiratory and cardiovascular systems have in common?
2. What structural and functional features are different in the upper and lower respiratory systems? Which are the same?
3. Compare the structure and functions of the external nose and the internal nose.

**Pharynx**

The pharynx (FAIR-inks), or throat, is a funnel-shaped tube about 13 cm (5 in.) long that starts at the internal nares and extends to the level of the cricoid cartilage, the most inferior cartilage of the larynx (voice box) (see Figure 23.2b). The phar-
yngx lies just posterior to the nasal and oral cavities, superior to the larynx, and just anterior to the cervical vertebrae. Its wall is composed of skeletal muscles and is lined with a mucous membrane. Contraction of the skeletal muscles assists in deglutition (swallowing). The pharynx functions as a passageway for air and food, provides a resonating chamber for speech sounds, and houses the tonsils, which participate in immunological reactions against foreign invaders.

The pharynx can be divided into three anatomical regions: (1) nasopharynx, (2) oropharynx, and (3) laryngopharynx. (See the lower orientation diagram in Figure 23.2b.) The muscles of the entire pharynx are arranged in two layers, an outer circular layer and an inner longitudinal layer.

The superior portion of the pharynx, called the nasopharynx, lies posterior to the nasal cavity and extends to the soft palate. The soft palate, which forms the posterior portion of the roof of the mouth, is an arch-shaped muscular partition between the nasopharynx and oropharynx that is lined by mucous membrane. There are five openings in its wall: two internal nares, two openings that lead into the auditory (pharyngotympanic) tubes (commonly known as the eustachian tubes), and the opening into the oropharynx. The posterior wall also contains the pharyngeal tonsil (adenoid). Through the internal nares, the nasopharynx receives air from the nasal cavity along with packages of dust-laden mucus. The nasopharynx is lined with pseudostratified ciliated columnar epithelium, and the cilia move the mucus down and out. The tonsils, primarily known as the tonsils, are found in the oropharynx.

The inferior portion of the pharynx, the oropharynx, lies posterior to the oral cavity and extends from the soft palate inferiorly to the level of the hyoid bone. It has only one opening into it, the faucae (FAW-sēz = throat), the opening from the mouth. This portion of the pharynx has both respiratory and digestive functions, serving as a common passageway for air, food, and drink. Because the oropharynx is subject to abrasion by food particles, it is lined with nonkeratinized stratified squamous epithelium. Two pairs of tonsils, the palatine and lingual tonsils, are found in the oropharynx.

The inferior portion of the pharynx, the laryngopharynx (lār-rin′-gō-FAIR-inks), or hypopharynx, begins at the level of the hyoid bone. At its inferior end it opens into the esophagus (food tube) posteriorly and the larynx (voice box) anteriorly. Like the oropharynx, the laryngopharynx is both a respiratory and a digestive pathway and is lined by nonkeratinized stratified squamous epithelium.

### Larynx

The larynx (LAIR-inks), or voice box, is a short passageway that connects the laryngopharynx with the trachea. It lies in the midline of the neck anterior to the esophagus and the fourth through sixth cervical vertebrae (C4–C6).

The wall of the larynx is composed of nine pieces of cartilage (Figure 23.4). Three occur singly (thyroid cartilage, epiglottis, and cricoid cartilage), and three occur in pairs (arytenoid, cuneiform, and corniculate cartilages). Of the paired cartilages, the arytenoid cartilages are the most important because they influence changes in position and tension of the vocal folds (true vocal cords for speech). The extrinsic muscles of the larynx connect the cartilages to other structures in the throat; the intrinsic muscles connect the cartilages to one another.

The thyroid cartilage (Adam’s apple) consists of two fused plates of hyaline cartilage that form the anterior wall of the larynx and give it a triangular shape. It is present in both males and females but is usually larger in males due to the influence of male sex hormones on its growth during puberty. The ligament that connects the thyroid cartilage to the hyoid bone is called the thyrohyoid membrane.

The epiglottis (epi- = over; glottis = glottis) is a large, leaf-shaped piece of elastic cartilage that is covered with epithelium (see also Figure 23.2b). The “stem” of the epiglottis is the tapered inferior portion that is attached to the anterior rim of the thyroid cartilage and hyoid bone. The broad superior “leaf” portion of the epiglottis is unattached and is free to move up and down like a trap door. During swallowing, the pharynx and larynx rise. Elevation of the pharynx widens it to receive food or drink; elevation of the larynx causes the epiglottis to move down and form a lid over the glottis, closing it off. The glottis consists of a pair of folds of mucous membrane, the vocal folds (true vocal cords) in the larynx, and the space between them called the rima glottidis (RI-ma GLOT-ti-dis). The closing of the larynx in this way during swallowing routes liquids and foods into the esophagus and keeps them out of the larynx and airways. When small particles of dust, smoke, food, or liquids pass into the larynx, a cough reflex occurs, usually expelling the material.

The cricoid cartilage (KRI-koyd = ringlike) is a ring of hyaline cartilage that forms the inferior wall of the larynx. It is attached to the first ring of cartilage of the trachea by the cricotracheal ligament. The thyroid cartilage is connected to the cricoid cartilage by the cricothyroid ligament. The cricoid cartilage is the landmark for making an emergency airway called a tracheotomy (see page 882).

The paired arytenoid cartilages (ar′-i-TÉ-noid = ladelike) are triangular pieces of mostly hyaline cartilage located at the posterior, superior border of the cricoid cartilage. They form synovial joints with the cricoid cartilage and have a wide range of mobility.

The paired corniculate cartilages (kor-NIK-ə-lát = shaped like a small horn), horn-shaped pieces of elastic cartilage, are located at the apex of each arytenoid cartilage. The paired...
CHAPTER 23 • THE RESPIRATORY SYSTEM

**cuneiform cartilages** (Kū-ne-i-form = wedge-shaped), club-shaped elastic cartilages anterior to the corniculate cartilages, support the vocal folds and lateral aspects of the epiglottis.

The lining of the larynx superior to the vocal folds is nonkeratinized stratified squamous epithelium. The lining of the larynx inferior to the vocal folds is pseudostratified ciliated columnar epithelium consisting of ciliated columnar cells, goblet cells, and basal cells. The mucus produced by the goblet cells helps trap dust not removed in the upper passages. The cilia in the upper respiratory tract move mucus and trapped particles _down_ toward the pharynx; the cilia in the lower respiratory tract move them _up_ toward the pharynx.

**Figure 23.4 Larynx.** (See Tortora, _A Photographic Atlas of the Human Body, Second Edition_, Figures 11.5 and 11.6.)

How does the epiglottis prevent aspiration of foods and liquids?

? How does the epiglottis prevent aspiration of foods and liquids?

The lining of the larynx superior to the vocal folds is nonkeratinized stratified squamous epithelium. The lining of the larynx inferior to the vocal folds is pseudostratified ciliated columnar epithelium consisting of ciliated columnar cells, goblet cells, and basal cells. The mucus produced by the goblet cells helps trap dust not removed in the upper passages. The cilia in the upper respiratory tract move mucus and trapped particles _down_ toward the pharynx; the cilia in the lower respiratory tract move them _up_ toward the pharynx.
The Structures of Voice Production

The mucous membrane of the larynx forms two pairs of folds (Figure 23.4c): a superior pair called the ventricular folds (false vocal cords) and an inferior pair called the vocal folds (true vocal cords). The space between the ventricular folds is known as the rima vestibuli. The laryngeal sinus (ventricle) is a lateral expansion of the middle portion of the laryngeal cavity inferior to the ventricular folds and superior to the vocal folds (see Figure 23.2b).

When the ventricular folds are brought together, they function in holding the breath against pressure in the thoracic cavity, such as might occur when you strain to lift a heavy object. Deep to the mucous membrane of the vocal folds, which is lined by nonkeratinized stratified squamous epithelium, bands of elastic ligaments are stretched between pieces of rigid cartilage like the strings on a guitar. Intrinsic laryngeal muscles attach to both the rigid cartilage and the vocal folds. When the muscles contract, they pull the elastic ligaments tight and stretch the vocal folds out into the airways so that the rima glottidis is narrowed. If air is directed against the vocal folds, they vibrate and produce sounds (phonation) by setting up sound waves in the column of air in the pharynx, nose, and mouth. The greater the pressure of air, the louder the sound.

When the intrinsic muscles of the larynx contract, they pull on the arytenoid cartilages, which causes them to pivot and slide. Contraction of the posterior cricoarytenoid muscles, for example, moves the vocal folds apart (abduction), thereby opening the rima glottidis (Figure 23.5a). By contrast, contraction of the lateral cricoarytenoid muscles moves the vocal folds together (adduction), thereby closing the rima glottidis (Figure 23.5b). Other intrinsic muscles can elongate (and place tension on) or shorten (and relax) the vocal folds.

Pitch is controlled by the tension on the vocal folds. If they are pulled taut by the muscles, they vibrate more rapidly, and a higher pitch results. Decreasing the muscular tension on the vocal folds causes them to vibrate more slowly and produce lower-pitch sounds. Due to the influence of androgens (male sex hormones), vocal folds are usually thicker and longer in males than in females, and therefore they vibrate more slowly. This is why a man’s voice generally has a lower range of pitch than that of a woman.
Sound originates from the vibration of the vocal folds, but other structures are necessary for converting the sound into recognizable speech. The pharynx, mouth, nasal cavity, and paranasal sinuses all act as resonating chambers that give the voice its human and individual quality. We produce the vowel sounds by constricting and relaxing the muscles in the wall of the pharynx. Muscles of the face, tongue, and lips help us enunciate words.

Whispering is accomplished by closing all but the posterior portion of the rima glottidis. Because the vocal folds do not vibrate during whispering, there is no pitch to this form of speech. However, we can still produce intelligible speech while whispering by changing the shape of the oral cavity as we enunciate. As the size of the oral cavity changes, its resonance qualities change, which imparts a vowel-like pitch to the air as it rushes toward the lips.

The layers of the tracheal wall, from deep to superficial, are the (1) mucosa, (2) submucosa, (3) hyaline cartilage, and (4) adventitia (composed of areolar connective tissue). The mucosa of the trachea consists of an epithelial layer of pseudostratified ciliated columnar epithelium and an underlying layer of lamina propria that contains elastic and reticular fibers. Pseudostratified ciliated columnar epithelium consists of ciliated columnar cells and goblet cells that reach the luminal surface, plus basal cells that do not (see Table 4.1E on page 117); it provides the same protection against dust as the membrane lining the nasal cavity and larynx. The submucosa consists of areolar connective tissue that contains seromucous glands and their ducts. The 16–20 incomplete, horizontal rings of hyaline cartilage resemble the letter C, are stacked one above another, and are connected together by dense connective tissue. They may be felt through the skin inferior to the larynx. The open part of each C-shaped cartilage ring faces posteriorly toward the esophagus (Figure 23.6) and is spanned by a fibromuscular membrane. Within this membrane are transverse smooth muscle fibers, called the trachealis muscle, and elastic connective tissue that allow the diameter of the trachea to change subtly during inhalation and exhalation, which is important in maintaining efficient airflow. The solid C-shaped cartilage rings provide a semirigid support so that the tracheal wall does not collapse inward (especially during inhalation) and obstruct the air passageway. The adventitia of the trachea consists of areolar connective tissue that joins the trachea to surrounding tissues.

What is the main function of the vocal folds?

The clinical connection of laryngitis and cancer of the larynx.

Laryngitis is an inflammation of the larynx that is most often caused by a respiratory infection or irritants such as cigarette smoke. Inflammation of the vocal folds causes hoarseness or loss of voice by interfering with the contraction of the folds or by causing them to swell to the point where they cannot vibrate freely. Many long-term smokers acquire a permanent hoarseness from the damage done by chronic inflammation. Cancer of the larynx is found almost exclusively in individuals who smoke. The condition is characterized by hoarseness, pain on swallowing, or pain radiating to an ear. Treatment consists of radiation therapy and/or surgery.

The clinical connection of tracheotomy and intubation.

Several conditions may block airflow by obstructing the trachea. For example, the rings of cartilage that support the trachea may collapse due to a crushing injury to the chest, inflammation of the mucous membrane may cause it to swell so much that the airway closes, vomit or a foreign object may be aspirated into it, or a cancerous tumor may protrude into the airway. Two methods are used to reestablish airflow past a tracheal obstruction. If the obstruction is superior to the level of the
**Figure 23.6 Location of the trachea in relation to the esophagus.**

The trachea is anterior to the esophagus and extends from the larynx to the superior border of the fifth thoracic vertebra.

---

**Bronchi**

At the superior border of the fifth thoracic vertebra, the trachea divides into a **right primary bronchus** (BRON-kus = wind-pipe), which goes into the right lung, and a **left primary bronchus**, which goes into the left lung (Figure 23.7). The right primary bronchus is more vertical, shorter, and wider than the left. As a result, an aspirated object is more likely to enter and lodge in the right primary bronchus than the left. Like the trachea, the primary bronchi (BRON-ke) contain incomplete rings of cartilage and are lined by pseudostratified ciliated columnar epithelium.

At the point where the trachea divides into right and left primary bronchi an internal ridge called the **carina** (ka-RI-na = keel of a boat) is formed by a posterior and somewhat inferior projection of the last tracheal cartilage. The mucous membrane of the carina is one of the most sensitive areas of the entire larynx and trachea for triggering a cough reflex. Widening and distortion of the carina is a serious sign because it usually indicates a carcinoma of the lymph nodes around the region where the trachea divides.

On entering the lungs, the primary bronchi divide to form smaller bronchi—the **secondary (lobar) bronchi**, one for each lobe of the lung. (The right lung has three lobes; the left lung has two.) The secondary bronchi continue to branch, forming still smaller bronchi, called **tertiary (segmental) bronchi**, that divide into **bronchioles**. Bronchioles in turn branch repeatedly, and the smallest ones branch into even smaller tubes called **terminal bronchioles**. This extensive branching from the trachea resembles an inverted tree and is commonly referred to as the **bronchial tree**.

As the branching becomes more extensive in the bronchial tree, several structural changes may be noted.

1. The mucous membrane in the bronchial tree changes from pseudostratified ciliated columnar epithelium in the primary bronchi, secondary bronchi, and tertiary bronchi to ciliated simple columnar epithelium with some goblet cells in larger bronchioles, to mostly ciliated simple cuboidal epithelium with no goblet cells in smaller bronchioles, to mostly nonciliated simple cuboidal epithelium in terminal bronchioles. (In regions where simple nonciliated cuboidal epithelium is present, inhaled particles are removed by macrophages.)
2. Plates of cartilage gradually replace the incomplete rings of cartilage in primary bronchi and finally disappear in the distal bronchioles.

3. As the amount of cartilage decreases, the amount of smooth muscle increases. Smooth muscle encircles the lumen in spiral bands. Because there is no supporting cartilage, however, muscle spasms can close off the airways. This is what happens during an asthma attack, which can be a life-threatening situation.

During exercise, activity in the sympathetic division of the autonomic nervous system (ANS) increases and the adrenal medulla releases the hormones epinephrine and norepinephrine; both of these events cause relaxation of smooth muscle in the bronchioles, which dilates the airways. Because air reaches the alveoli more quickly, lung ventilation improves. The parasympathetic division of the ANS and mediators of allergic reactions such as histamine have the opposite effect, causing contraction of bronchiolar smooth muscle, which results in constriction of distal bronchioles.

**CHECKPOINT**

4. List the roles of each of the three anatomical regions of the pharynx in respiration.

5. How does the larynx function in respiration and voice production?

6. Describe the location, structure, and function of the trachea.

7. Describe the structure of the bronchial tree.
**Lungs**

The lungs (= lightweights, because they float) are paired cone-shaped organs in the thoracic cavity. They are separated from each other by the heart and other structures in the mediastinum, which divides the thoracic cavity into two anatomically distinct chambers. As a result, if trauma causes one lung to collapse, the other may remain expanded. Each lung is enclosed and protected by a double-layered serous membrane called the *pleural membrane* (PLOOR-al; pleur- = side). The superficial layer, called the *parietal pleura*, lines the wall of the thoracic cavity; the deep layer, the *visceral pleura*, covers the lungs themselves (Figure 23.8). Between the visceral and parietal pleurae is a small space, the *pleural cavity*, which contains a small amount of lubricating fluid secreted by the membranes. This pleural fluid reduces friction between the membranes, allowing them to slide easily over one another during breathing. Pleural fluid also causes the two membranes to adhere to one another just as a film of water causes two glass microscope slides to stick together, a phenomenon called surface tension. Separate pleural cavities surround the left and right lungs. Inflammation of the pleural membrane, called *pleurisy* or *pleuritis*, may in its early stages cause pain due to friction between the parietal and visceral layers of the pleura. If the inflammation persists, excess fluid accumulates in the pleural space, a condition known as *pleural effusion*.

**Figure 23.8  Relationship of the pleural membranes to the lungs.**

The parietal pleura lines the thoracic cavity, and the visceral pleura covers the lungs.

---

**CLINICAL CONNECTION  Pneumothorax and Hemothorax**

In certain conditions, the pleural cavities may fill with air (*pneumothorax*; pneumo- = air or breath), blood (*hemothorax*), or pus. Air in the pleural cavities, most commonly introduced in a surgical opening of the chest or as a result of a stab or gunshot wound, may cause the lungs to collapse. This collapse of a part of a lung, or rarely an entire lung, is called *atelectasis* (at’-e-LEK-ta-sis; atele- = incomplete; -ectasis- = expansion). The goal of treatment is the evacuation of air (or blood) from the pleural space, which allows the lung to reinflate. A small pneumothorax may resolve on its own, but it is often necessary to insert a chest tube to assist in evacuation.

The lungs extend from the diaphragm to just slightly superior to the clavicles and lie against the ribs anteriorly and posteriorly (Figure 23.9a). The broad inferior portion of the lung, the *base*, is concave and fits over the convex area of the diaphragm. The narrow superior portion of the lung is the *apex*. The surface of the lung lying against the ribs, the *costal surface*, matches the rounded curvature of the ribs. The *mediastinal (medial) surface* of each lung contains a region, the *hilum*, through which bronchi, pulmonary blood vessels, lymphatic vessels, and nerves enter and exit (Figure 23.9e). These structures are held together by the pleura and connective tissue and constitute the *root* of the
Figure 23.9 Surface anatomy of the lungs. (See Tortora, A Photographic Atlas of the Human Body, Second Edition, Figures 11.12 and 11.14.)

The oblique fissure divides the left lung into two lobes. The oblique and horizontal fissures divide the right lung into three lobes.

Why are the right and left lungs slightly different in size and shape?

The lungs almost fill the thorax (Figure 23.9a). The apex of the lungs lies superior to the medial third of the clavicles and is what shorter than the left lung because the diaphragm is higher on the right side, accommodating the liver that lies inferior to it.

Medially, the left lung also contains a concavity, the cardiac notch, in which the heart lies. Due to the space occupied by the heart, the left lung is about 10% smaller than the right lung. Although the right lung is thicker and broader, it is also some-
the only area that can be palpated. The anterior, lateral, and posterior surfaces of the lungs lie against the ribs. The base of the lungs extends from the sixth costal cartilage anteriorly to the spinous process of the tenth thoracic vertebra posteriorly. The pleura extends about 5 cm (2 in.) below the base from the sixth costal cartilage anteriorly to the twelfth rib posteriorly. Thus, the lungs do not completely fill the pleural cavity in this area. Removal of excessive fluid in the pleural cavity can be accomplished without injuring lung tissue by inserting a needle anteriorly through the seventh intercostal space, a procedure called \textit{thoracentesis} (thor-a-sen-TE-sis; -centesis = puncture). The needle is passed along the superior border of the lower rib to avoid damage to the intercostal nerves and blood vessels. Inferior to the seventh intercostal space there is danger of penetrating the diaphragm.

\textbf{Lobes, Fissures, and Lobules}

One or two fissures divide each lung into lobes (Figure 23.9b–e). Both lungs have an \textit{oblique fissure}, which extends inferiorly and anteriorly; the right lung also has a \textit{horizontal fissure}. The oblique fissure in the left lung separates the \textit{superior lobe} from the \textit{inferior lobe}. In the right lung, the superior part of the oblique fissure separates the superior lobe from the inferior lobe; the inferior part of the oblique fissure separates the inferior lobe from the \textit{middle lobe}, which is bordered superiorly by the horizontal fissure.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{lobes_fissures_lobules.png}
\caption{Microscopic anatomy of a lobule of the lungs.}
\end{figure}

Each lobe receives its own secondary (lobar) bronchus. Thus, the right primary bronchus gives rise to three secondary (lobar) bronchi called the \textit{superior, middle, and inferior secondary (lobar) bronchi}, and the left primary bronchus gives rise to \textit{superior and inferior secondary (lobar) bronchi}. Within the lung, the secondary bronchi give rise to the \textit{tertiary (segmental) bronchi}, which are constant in both origin and distribution—there are 10 tertiary bronchi in each lung. The segment of lung tissue that each tertiary bronchus supplies is called a \textbf{bronchopulmonary segment}. Bronchial and pulmonary disorders (such as tumors or abscesses) that are localized in a bronchopulmonary segment may be surgically removed without seriously disrupting the surrounding lung tissue.

Each bronchopulmonary segment of the lungs has many small compartments called \textit{lobules}; each lobule is wrapped in elastic connective tissue and contains a lymphatic vessel, an arteriole, a venule, and a branch from a terminal bronchiole (Figure 23.10a). Terminal bronchioles subdivide into microscopic branches called \textit{respiratory bronchioles} (Figure 23.10b). As the respiratory bronchioles penetrate more deeply into the lungs, the epithelial lining changes from simple cuboidal to simple squamous. Respiratory bronchioles in turn subdivide into several (2–11) \textit{alveolar ducts}. The respiratory passages from the trachea to the alveolar ducts contain about 25 orders of branching; branching from the trachea into primary bronchi is called first-order branching, from primary bronchi into secondary

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{alveoli.png}
\caption{What types of cells make up the wall of an alveolus?}
\end{figure}
The exchange of respiratory gases occurs by diffusion across the respiratory membrane.

**Figure 23.11** Structural components of an alveolus. The respiratory membrane consists of a layer of type I and type II alveolar cells, an epithelial basement membrane, a capillary basement membrane, and the capillary endothelium.
1. A layer of type I and type II alveolar cells and associated alveolar macrophages that constitutes the **alveolar wall**

2. An **epithelial basement membrane** underlying the alveolar wall

3. A **capillary basement membrane** that is often fused to the epithelial basement membrane

4. The **capillary endothelium**

   Despite having several layers, the respiratory membrane is very thin—only 0.5 μm thick, about one-sixteenth the diameter of a red blood cell—to allow rapid diffusion of gases. It has been estimated that the lungs contain 300 million alveoli, providing an immense surface area of 70 m² (750 ft²)—about the size of a racquetball court—for gas exchange.

**Blood Supply to the Lungs**

The lungs receive blood via two sets of arteries: pulmonary arteries and bronchial arteries. Deoxygenated blood passes through the pulmonary trunk, which divides into a left pulmonary artery that enters the left lung and a right pulmonary artery that enters the right lung. (The pulmonary arteries are the only arteries in the body that carry deoxygenated blood.) Return of the oxygenated blood to the heart occurs by way of the four pulmonary veins, which drain into the left atrium (see Figure 21.29 on page 820). A unique feature of pulmonary blood vessels is their constriction in response to localized hypoxia (low O₂ level). In all other body tissues, hypoxia causes dilation of blood vessels to increase blood flow. In the lungs, however, vasoconstriction in response to hypoxia diverts pulmonary blood from poorly ventilated areas of the lungs to well-ventilated regions. This phenomenon is known as **ventilation-perfusion coupling** because the perfusion (blood flow) to each area of the lungs matches the extent of ventilation (airflow) to alveoli in that area.

Bronchial arteries, which branch from the aorta, deliver oxygenated blood to the lungs. This blood mainly perfuses the muscular walls of the bronchi and bronchioles. Connections exist between branches of the bronchial arteries and branches of the pulmonary arteries, however; most blood returns to the heart via pulmonary veins. Some blood, however, drains into bronchial veins, branches of the azygos system, and returns to the heart via the superior vena cava.

**CHECKPOINT**

8. Where are the lungs located? Distinguish the parietal pleura from the visceral pleura.
9. Define each of the following parts of a lung: base, apex, costal surface, medial surface, hilum, root, cardiac notch, lobe, and lobule.
10. What is a bronchopulmonary segment?
11. Describe the histology and function of the respiratory membrane.

**How thick is the respiratory membrane?**
PULMONARY VENTILATION

**OBJECTIVE**
- Describe the events that cause inhalation and exhalation.

The process of gas exchange in the body, called **respiration**, has three basic steps:

1. **Pulmonary ventilation** (pulmon- = lung), or **breathing**, is the **inhalation** (inflow) and exhalation (outflow) of air and involves the exchange of air between the atmosphere and the alveoli of the lungs.

2. **External (pulmonary) respiration** is the exchange of gases between the alveoli of the lungs and the blood in pulmonary capillaries across the respiratory membrane. In this process, pulmonary capillary blood gains O₂ and loses CO₂.

3. **Internal (tissue) respiration** is the exchange of gases between blood in systemic capillaries and tissue cells. In this step, the blood loses O₂ and gains CO₂. Within cells, the metabolic reactions that consume O₂ and give off CO₂ during the production of ATP are termed **cellular respiration** (discussed in Chapter 25).

In pulmonary ventilation, air flows between the atmosphere and the alveoli of the lungs because of alternating pressure differences created by contraction and relaxation of respiratory muscles. The rate of airflow and the amount of effort needed for breathing is also influenced by alveolar surface tension, compliance of the lungs, and airway resistance.

**Pressure Changes During Pulmonary Ventilation**

Air moves into the lungs when the air pressure inside the lungs is less than the air pressure in the atmosphere. Air moves out of the lungs when the air pressure inside the lungs is greater than the air pressure in the atmosphere.

**Inhalation**

Breathing in is called **inhalation** (**inspiration**). Just before each inhalation, the air pressure inside the lungs is equal to the air pressure of the atmosphere, which at sea level is about 760 millimeters of mercury (mmHg), or 1 atmosphere (atm). For air to flow into the lungs, the pressure inside the alveoli must become lower than the atmospheric pressure. This condition is achieved by increasing the size of the lungs.

The pressure of a gas in a closed container is inversely proportional to the volume of the container. This means that if the size of a closed container is increased, the pressure of the gas inside the container decreases, and if the size of the container is decreased, then the pressure inside it increases. This inverse relationship between volume and pressure, called Boyle’s law, may be demonstrated as follows (Figure 23.12): Suppose we place a gas in a cylinder that has a movable piston and a pressure gauge, and that the initial pressure created by the gas molecules striking the wall of the container is 1 atm. If the piston is pushed down, the gas is compressed into a smaller volume, so that the same number of gas molecules strike less wall area. The gauge shows that the pressure doubles as the gas is compressed to half its original volume. In other words, the same number of molecules in half the volume produces twice the pressure. Conversely, if the piston is raised to increase the volume, the pressure decreases. Thus, the pressure of a gas varies inversely with volume.

Differences in pressure caused by changes in lung volume force air into our lungs when we inhale and out when we exhale. For inhalation to occur, the lungs must expand, which increases lung volume and thus decreases the pressure in the lungs to below atmospheric pressure. The first step in expanding the lungs during normal quiet inhalation involves contraction of the main muscles of inhalation, the diaphragm and external intercostals (Figure 23.13).

The most important muscle of inhalation is the diaphragm, the dome-shaped skeletal muscle that forms the floor of the thoracic cavity. It is innervated by fibers of the phrenic nerves, which emerge from the spinal cord at cervical levels 3, 4, and 5. Contraction of the diaphragm causes it to flatten, lowering its dome. This increases the vertical diameter of the thoracic cavity. During normal quiet inhalation, the diaphragm descends about 1 cm (0.4 in.), producing a pressure difference of 1–3 mmHg and the inhalation of about 500 mL of air. In strenuous breathing, the diaphragm may descend 10 cm (4 in.), which produces a pressure difference of 100 mmHg and the inhalation of 2–3 liters of air. Contraction of the diaphragm is responsible for about 75% of the air that enters the lungs during quiet breathing. Advanced pregnancy, excessive obesity, or confining abdominal clothing can prevent complete descent of the diaphragm.

The next most important muscles of inhalation are the external intercostals. When these muscles contract, they elevate the ribs. As a result, there is an increase in the anteroposterior and lateral diameters of the chest cavity. Contraction of the external intercostals is responsible for about 25% of the air that enters the lungs during normal quiet breathing.
During quiet inhalations, the pressure between the two pleural layers in the pleural cavity, called intrapleural (intrathoracic) pressure, is always subatmospheric (lower than atmospheric pressure). Just before inhalation, it is about 4 mmHg less than the atmospheric pressure, or about 756 mmHg at an atmospheric pressure of 760 mmHg (Figure 23.14). As the diaphragm and external intercostals contract and the overall size of the thoracic cavity increases, the volume of the pleural cavity also increases, which causes intrapleural pressure to decrease to about 754 mmHg. During expansion of the thorax, the parietal and visceral pleurae normally adhere tightly because of the subatmospheric pressure between them and because of the surface tension created by their moist adjoining surfaces. As the thoracic cavity expands, the parietal pleura lining the cavity is pulled outward in all directions, and the visceral pleura and lungs are pulled along with it.

As the volume of the lungs increases in this way, the pressure inside the lungs, called alveolar (intrapulmonic) pressure, drops from 760 to 758 mmHg. A pressure difference is thus established between the atmosphere and the alveoli. Because air
always flows from a region of higher pressure to a region of lower pressure, inhalation takes place. Air continues to flow into the lungs as long as a pressure difference exists. During deep, forceful inhalations, accessory muscles of inspiration also participate in increasing the size of the thoracic cavity (see Figure 23.13a). The muscles are so named because they make little, if any, contribution during normal quiet inhalation, but during exercise or forced ventilation they may contract vigorously. The accessory muscles of inhalation include the sternocleidomastoid muscles, which elevate the sternum; the scalene muscles, which elevate the first two ribs; and the pectoralis minor muscles, which elevate the third through fifth ribs. Because both normal quiet inhalation and inhalation during exercise or forced ventilation involve muscular contraction, the process of inhalation is said to be active.

How does the intrapleural pressure change during a normal, quiet breath?

Exhalation

Breathing out, called exhalation (expiration), is also due to a pressure gradient, but in this case the gradient is in the opposite direction: The pressure in the lungs is greater than the pressure of the atmosphere. Normal exhalation during quiet breathing, unlike inhalation, is a passive process because no muscular contractions are involved. Instead, exhalation results from elastic recoil of the chest wall and lungs, both of which have a natural tendency to spring back after they have been stretched. Two inwardly directed forces contribute to elastic recoil: (1) the recoil of elastic fibers that were stretched during inhalation and (2) the inward pull of surface tension due to the film of alveolar fluid.

Exhalation starts when the inspiratory muscles relax. As the diaphragm relaxes, its dome moves superiorly owing to its elasticity. As the external intercostals relax, the ribs are

Figure 23.15a summarizes the events of inhalation.
depressed. These movements decrease the vertical, lateral, and anteroposterior diameters of the thoracic cavity, which decreases lung volume. In turn, the alveolar pressure increases to about 762 mmHg. Air then flows from the area of higher pressure in the alveoli to the area of lower pressure in the atmosphere (see Figure 23.14).

Exhalation becomes active only during forceful breathing, as occurs while playing a wind instrument or during exercise. During these times, muscles of exhalation—the abdominals and internal intercostals (see Figure 23.13a) — contract, which increases pressure in the abdominal region and thorax. Contraction of the abdominal muscles moves the inferior ribs downward and compresses the abdominal viscera, thereby forcing the diaphragm superiorly. Contraction of the internal intercostals, which extend inferiorly and posteriorly between adjacent ribs, pulls the ribs inferiorly. Although intrapleural pressure is always less than alveolar pressure, it may briefly exceed atmospheric pressure during a forceful exhalation, such as during a cough.

Figure 23.15b summarizes the events of exhalation.

Other Factors Affecting Pulmonary Ventilation

As you have just learned, air pressure differences drive airflow during inhalation and exhalation. However, three other factors affect the rate of airflow and the ease of pulmonary ventilation: surface tension of the alveolar fluid, compliance of the lungs, and airway resistance.

Surface Tension of Alveolar Fluid

As noted earlier, a thin layer of alveolar fluid coats the luminal surface of alveoli and exerts a force known as surface tension. Surface tension arises at all air–water interfaces because the polar water molecules are more strongly attracted to each other than they are to gas molecules in the air. When liquid surrounds a sphere of air, as in an alveolus or a soap bubble, surface tension produces an inwardly directed force. Soap bubbles “burst” because they collapse inward due to surface tension. In the lungs, surface tension causes the alveoli to assume the smallest possible diameter. During breathing, surface tension must be overcome to expand the lungs during each inhalation. Surface tension also accounts for two-thirds of lung elastic recoil, which decreases the size of alveoli during exhalation.

The surfactant (a mixture of phospholipids and lipoproteins) present in alveolar fluid reduces its surface tension below the surface tension of pure water. A deficiency of surfactant in premature infants causes respiratory distress syndrome, in which the surface tension of alveolar fluid is greatly increased, so that many alveoli collapse at the end of each exhalation. Great effort is then needed at the next inhalation to reopen the collapsed alveoli.
Respiratory distress syndrome (RDS) is a breathing disorder of premature newborns in which the alveoli do not remain open due to a lack of surfactant. Recall that surfactant reduces surface tension and is necessary to prevent the collapse of alveoli during exhalation. The more premature the newborn, the greater the chance that RDS will develop. The condition is also more common in infants whose mothers have diabetes, in males, and occurs more often in European Americans than African Americans. Symptoms of RDS include labored and irregular breathing, flaring of the nostrils during inhalation, grunting during exhalation, and perhaps a blue skin color. Besides the symptoms, RDS is diagnosed on the basis of chest radiographs and a blood test. A newborn with mild RDS may require only supplemental oxygen administered through an oxygen hood or through a tube placed in the nose. In severe cases oxygen may be delivered by continuous positive airway pressure (CPAP) through tubes in the nostrils or a mask on the face.

Any condition that narrows or obstructs the airways increases resistance, so that more pressure is required to maintain the same airflow. The hallmark of asthma or chronic obstructive pulmonary disease (COPD)—emphysema or chronic bronchitis—is increased airway resistance due to obstruction or collapse of airways.

Breathing Patterns and Modified Respiratory Movements

The term for the normal pattern of quiet breathing is eupnea (up-NEE-a; eu- = good, easy, or normal; -pnea = breath). Eupnea can consist of shallow, deep, or combined shallow and deep breathing. A pattern of shallow (chest) breathing, called costal breathing, consists of an upward and outward movement of the chest due to contraction of the external intercostal muscles. A pattern of deep (abdominal) breathing, called diaphragmatic breathing, consists of the outward movement of the abdomen due to the contraction and descent of the diaphragm.

Respirations also provide humans with methods for expressing emotions such as laughing, sighing, and sobbing. Moreover, respiratory air can be used to expel foreign matter from the lower air passages through actions such as sneezing and coughing. Respiratory movements are also modified and controlled during talking and singing. Some of the modified respiratory movements that express emotion or clear the airways are listed in Table 23.1. All these movements are reflexes, but some of them also can be initiated voluntarily.

LUNG VOLUMES AND CAPACITIES

Objectives

- Explain the difference between tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume.
- Differentiate between inspiratory capacity, functional residual capacity, vital capacity, and total lung capacity.

While at rest, a healthy adult averages 12 breaths a minute, with each inhalation and exhalation moving about 500 mL of air into and out of the lungs. The volume of one breath is called the tidal volume (V_t). The minute ventilation (MV)—the total volume of air inhaled and exhaled each minute—is respiratory rate multiplied by tidal volume:

\[
MV = 12 \text{ breaths/min} \times 500 \text{ mL/breath} = 6 \text{ liters/min}
\]
A lower-than-normal minute ventilation usually is a sign of pulmonary malfunction. The apparatus commonly used to measure the volume of air exchanged during breathing and the respiratory rate is a spirometer (spiro- = breathe; meter = measuring device) or respirometer. The record is called a spirogram. Inhalation is recorded as an upward deflection, and exhalation is recorded as a downward deflection (Figure 23.16).

Tidal volume varies considerably from one person to another and in the same person at different times. In a typical adult, about 70% of the tidal volume (350 mL) actually reaches the lungs.

### Figure 23.16 Spirogram of lung volumes and capacities.

Lung capacities are combinations of various lung volumes.

If you breathe in as deeply as possible and then exhale as much air as you can, which lung capacity have you demonstrated?
respiratory zone of the respiratory system—the respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli—and participates in external respiration. The other 30% (150 mL) remains in the conducting airways of the nose, pharynx, larynx, trachea, bronchi, bronchioles, and terminal bronchioles. Collectively, the conducting airways with air that does not undergo respiratory exchange are known as the anatomic (respiratory) dead space. (An easy rule of thumb for determining the volume of your anatomic dead space is that it is about the same in milliliters as your ideal weight in pounds.) Not all of the volume of your anatomic dead space is that it is about the same in milliliters as your ideal weight in pounds.) Not all of the minute ventilation can be used in gas exchange because some of it remains in the anatomic dead space. The alveolar ventilation rate is the volume of air per minute that actually reaches the respiratory zone. In the example just given, alveolar ventilation rate would be 350 mL/breath × 12 breaths/min = 4200 mL/min.

Several other lung volumes are defined relative to forceful breathing. In general, these volumes are larger in males, taller individuals, and younger adults, and smaller in females, shorter individuals, and the elderly. Various disorders also may be diagnosed by comparison of actual and predicted normal values for a patient’s gender, height, and age. The values given here are averages for young adults.

By taking a very deep breath, you can inhale a good deal more than 500 mL. This additional inhaled air, called the inspiratory reserve volume, is about 3100 mL in an average adult male and 1900 mL in an average adult female (Figure 23.16). Even more air can be inhaled if inhalation follows forced exhalation. If you inhale normally and then exhale as forcibly as possible, you should be able to push out considerably more air in addition to the 500 mL of tidal volume. The extra 1200 mL in males and 700 mL in females is called the expiratory reserve volume. The FEV1.0 is the forced expiratory volume in 1 second, the volume of air that can be exhaled from the lungs in 1 second with maximal effort following a maximal inhalation. Typically, chronic obstructive pulmonary disease (COPD) greatly reduces FEV1.0 because COPD increases airway resistance.

Even after the expiratory reserve volume is exhaled, considerate air remains in the lungs because the subatmospheric intrapleural pressure keeps the alveoli slightly inflated, and some air also remains in the noncollapsible airways. This volume, which cannot be measured by spirometry, is called the residual volume and amounts to about 1200 mL in males and 1100 mL in females.

If the thoracic cavity is opened, the intrapleural pressure rises to equal the atmospheric pressure and forces out some of the residual volume. The air remaining is called the minimal volume. Minimal volume provides a medical and legal tool for determining whether a baby is born dead (stillborn) or died after birth. The presence of minimal volume can be demonstrated by placing a piece of lung in water and observing if it floats. Fetal lungs contain no air, so the lung of a stillborn baby will not float in water.

Lung capacities are combinations of specific lung volumes (Figure 23.16). Inspiratory capacity is the sum of tidal volume and inspiratory reserve volume (500 mL + 3100 mL = 3600 mL in males and 500 mL + 1900 mL = 2400 mL in females). Functional residual capacity is the sum of residual volume and expiratory reserve volume (1200 mL + 1200 mL = 2400 mL in males and 1100 mL + 700 mL = 1800 mL in females). Vital capacity is the sum of inspiratory reserve volume, tidal volume, and expiratory reserve volume (4800 mL in males and 3100 mL in females). Finally, total lung capacity is the sum of vital capacity and residual volume (4800 mL + 1200 mL = 6000 mL in males and 3100 mL + 1100 mL = 4200 mL in females).

CHECKPOINT

18. How is minute ventilation calculated?
19. Define alveolar ventilation rate and FEV1.0.

EXCHANGE OF OXYGEN AND CARBON DIOXIDE

OBJECTIVES
• Explain Dalton’s law and Henry’s law.
• Describe the exchange of oxygen and carbon dioxide in external and internal respiration.

The exchange of oxygen and carbon dioxide between alveolar air and pulmonary blood occurs via passive diffusion, which is governed by the behavior of gases as described by two gas laws, Dalton’s law and Henry’s law. Dalton’s law is important for understanding how gases move down their pressure differences by diffusion, and Henry’s law helps explain how the solubility of a gas relates to its diffusion.

Gas Laws: Dalton’s Law and Henry’s Law

According to Dalton’s law, each gas in a mixture of gases exerts its own pressure as if no other gases were present. The pressure of a specific gas in a mixture is called its partial pressure (P); the subscript is the chemical formula of the gas. The total pressure of the mixture is calculated simply by adding all the partial pressures. Atmospheric air is a mixture of gases—nitrogen (N2), oxygen (O2), water vapor (H2O), and carbon dioxide (CO2), plus other gases present in small quantities. Atmospheric pressure is the sum of the pressures of all these gases:

Atmospheric pressure (760 mmHg)

= P N + P O + P H O + P CO + P other gases

We can determine the partial pressure exerted by each component in the mixture by multiplying the percentage of the gas in the mixture by the total pressure of the mixture. Atmospheric air is 78.6% nitrogen, 20.9% oxygen, 0.04% carbon dioxide, and 0.06% other gases; a variable amount of water vapor is also present, about 0.4% on a cool, dry day. Thus, the
full solution. In comparison to oxygen, much more CO₂ is gas over a liquid and the higher the solubility, the more gas will have a high solubility in water. The higher the partial pressure of a solution is greater when its partial pressure is higher and when it

exhaled air was in the anatomic dead space and did not participate in gas exchange. Exhaled air is a mixture of alveolar air and inhaled air that was in the anatomic dead space.

Henry’s law states that the quantity of a gas that will dissolve in a liquid is proportional to the partial pressure of the gas and its solubility. In body fluids, the ability of a gas to stay in solution is greater when its partial pressure is higher and when it has a high solubility in water. The higher the partial pressure of a gas over a liquid and the higher the solubility, the more gas will stay in solution. In comparison to oxygen, much more CO₂ is dissolved in blood plasma because the solubility of CO₂ is 24 times greater than that of O₂. Even though the air we breathe contains mostly N₂, this gas has no known effect on bodily functions, and at sea level pressure very little of it dissolves in blood plasma because its solubility is very low.

An everyday experience gives a demonstration of Henry’s law. You have probably noticed that a soft drink makes a hissing sound when the top of the container is removed, and bubbles rise to the surface for some time afterward. The gas dissolved in carbonated beverages is CO₂. Because the soft drink is bottled or canned under high pressure and capped, the CO₂ remains dissolved as long as the container is unopened. Once you remove the cap, the pressure decreases and the gas begins to bubble out of solution.

Henry’s law explains two conditions resulting from changes in the solubility of nitrogen in body fluids. Even though the air we breathe contains about 79% nitrogen, this gas has no known effect on bodily functions, and very little of it dissolves in blood plasma because of its low solubility at sea level pressure. As the total air pressure increases, the partial pressures of all its gases increase. When a scuba diver breathes air under high pressure, the nitrogen in the mixture can have serious negative effects.

Because the partial pressure of nitrogen is higher in a mixture of compressed air than in air at sea level pressure, a considerable amount of nitrogen dissolves in plasma and interstitial fluid. Excessive amounts of dissolved nitrogen may produce giddiness and other symptoms similar to alcohol intoxication. The condition is called nitrogen narcosis or “rapture of the deep.”

If a diver comes to the surface slowly, the dissolved nitrogen can be eliminated by exhaling it. However, if the ascent is too rapid, nitrogen comes out of solution too quickly and forms gas bubbles in the tissues, resulting in decompression sickness (the bends). The effects of decompression sickness typically result from bubbles in nervous tissue and can be mild or severe, depending on the number of bubbles formed. Symptoms include joint pain, especially in the arms and legs, dizziness, shortness of breath, extreme fatigue, paralysis, and unconsciousness.

**CLINICAL CONNECTION** | Hyperbaric Oxygenation
---
A major clinical application of Henry’s law is hyperbaric oxygenation (hyp = hyper; bar = pressure), the use of pressure to cause more O₂ to dissolve in the blood. It is an effective technique in treating patients infected by anaerobic bacteria, such as those that cause tetanus and gangrene. (Anaerobic bacteria cannot live in the presence of free O₂.) A person undergoing hyperbaric oxygenation is placed in a hyperbaric chamber, which contains O₂ at a pressure greater than one atmosphere (760 mmHg). As body tissues pick up the O₂, the bacteria are killed. Hyperbaric chambers may also be used for treating certain heart disorders, carbon monoxide poisoning, gas embolisms, crush injuries, cerebral edema, certain hard-to-treat bone infections caused by anaerobic bacteria, smoke inhalation, near-drowning, asphyxia, vascular insufficiencies, and burns.

**External and Internal Respiration**

External respiration or pulmonary gas exchange is the diffusion of O₂ from air in the alveoli of the lungs to blood in pulmonary capillaries and the diffusion of CO₂ in the opposite direction (Figure 23.17a). External respiration in the lungs converts deoxygenated blood (depleted of some O₂) coming from the right side of the heart into oxygenated blood (saturated with O₂) that returns to the left side of the heart (see Figure 21.29 on page 820). As blood flows through the pulmonary capillaries, it picks up O₂ from alveolar air and unloads CO₂ into alveolar air. Although this process is commonly called an “exchange” of gases, each gas diffuses independently from the area where its partial pressure is higher to the area where its partial pressure is lower.

As Figure 23.17a shows, O₂ diffuses from alveolar air, where its partial pressure is 105 mmHg, into the blood in pulmonary capillaries, where PₐO₂ is only 40 mmHg in a resting person. If you have been exercising, the PₐO₂ will be even lower because contracting muscle fibers are using more O₂. Diffusion continues until the P₀₂ of pulmonary capillary blood increases to match the Pₒ₂ of alveolar air, 105 mmHg. Because blood leaving pulmonary capillaries near alveolar air spaces mixes with a small
volume of blood that has flowed through conducting portions of the respiratory system, where gas exchange does not occur, the \( P_{O_2} \) of blood in the pulmonary veins is slightly less than the \( P_{O_2} \) in pulmonary capillaries, about 100 mmHg.

While \( O_2 \) is diffusing from alveolar air into deoxygenated blood, \( CO_2 \) is diffusing in the opposite direction. The \( P_{CO_2} \) of deoxygenated blood is 45 mmHg in a resting person, and the \( P_{CO_2} \) of alveolar air is 40 mmHg. Because of this difference in

What causes oxygen to enter pulmonary capillaries from alveoli and to enter tissue cells from systemic capillaries?
$P_{CO_2}$, carbon dioxide diffuses from deoxygenated blood into the alveoli until the $P_{CO_2}$ of the blood decreases to 40 mmHg. Exhalation keeps alveolar $P_{CO_2}$ at 40 mmHg. Oxygenated blood returning to the left side of the heart in the pulmonary veins thus has a $P_{CO_2}$ of 40 mmHg.

The number of capillaries near alveoli in the lungs is very large, and blood flows slowly enough through these capillaries that it picks up a maximal amount of $O_2$. During vigorous exercise, when cardiac output is increased, blood flows more rapidly through both the systemic and pulmonary circulations. As a result, blood’s transit time in the pulmonary capillaries is shorter. Still, the $P_{O_2}$ of blood in the pulmonary veins normally reaches 100 mmHg. In diseases that decrease the rate of gas diffusion, however, the blood may not come into full equilibrium with alveolar air, especially during exercise. When this happens, the $P_{O_2}$ declines and $P_{CO_2}$ rises in systemic arterial blood.

The left ventricle pumps oxygenated blood into the aorta and through the systemic arteries to systemic capillaries. The exchange of $O_2$ and $CO_2$ between systemic capillaries and tissue cells is called internal respiration or systemic gas exchange (Figure 23.17b). As $O_2$ leaves the bloodstream, oxygenated blood is converted into deoxygenated blood. Unlike external respiration, which occurs only in the lungs, internal respiration occurs in tissues throughout the body.

The $P_{O_2}$ of blood pumped into systemic capillaries is higher (100 mmHg) than the $P_{O_2}$ in tissue cells (40 mmHg at rest) because the cells constantly use $O_2$ to produce ATP. Due to this pressure difference, oxygen diffuses out of the capillaries into tissue cells and blood $P_{O_2}$ drops to 40 mmHg by the time the blood exits systemic capillaries.

While $O_2$ diffuses from the systemic capillaries into tissue cells, $CO_2$ diffuses in the opposite direction. Because tissue cells are constantly producing $CO_2$, the $P_{CO_2}$ of cells (45 mmHg at rest) is higher than that of systemic capillary blood (40 mmHg). As a result, $CO_2$ diffuses from tissue cells through interstitial fluid into systemic capillaries until the $P_{CO_2}$ in the blood increases to 45 mmHg. The deoxygenated blood then returns to the heart and is pumped to the lungs for another cycle.

In a person at rest, tissue cells, on average, need only 25% of the available $O_2$ in oxygenated blood; despite its name, deoxygenated blood retains 75% of its $O_2$ content. During exercise, more $O_2$ diffuses from the blood into metabolically active cells, such as contracting skeletal muscle fibers. Active cells use more $O_2$ for ATP production, causing the $O_2$ content of deoxygenated blood to drop below 75%.

The rate of pulmonary and systemic gas exchange depends on several factors.

- **Partial pressure difference of the gases.** Alveolar $P_{O_2}$ must be higher than blood $P_{O_2}$ for oxygen to diffuse from alveolar air into the blood. The rate of diffusion is faster when the difference between $P_{O_2}$ in alveolar air and pulmonary capillary blood is larger; diffusion is slower when the difference is smaller. The differences between $P_{O_2}$ and $P_{CO_2}$ in alveolar air versus pulmonary blood increase during exercise. The larger partial pressure differences accelerate the rates of gas diffusion. The partial pressures of $O_2$ and $CO_2$ in alveolar air also depend on the rate of airflow into and out of the lungs. Certain drugs (such as morphine) slow ventilation, thereby decreasing the amount of $O_2$ and $CO_2$ that can be exchanged between alveolar air and blood. With increasing altitude, the total atmospheric pressure decreases, as does the partial pressure of $O_2$—from 159 mmHg at sea level, to 110 mmHg at 10,000 ft, to 73 mmHg at 20,000 ft. Although $O_2$ still is 20.9% of the total, the $P_{O_2}$ of inhaled air decreases with increasing altitude. Alveolar $P_{O_2}$ decreases correspondingly, and $O_2$ diffuses into the blood more slowly. The common signs and symptoms of high altitude sickness—shortness of breath, headache, fatigue, insomnia, nausea, and dizziness—are due to a lower level of oxygen in the blood.

- **Diffusion distance.** The respiratory membrane is very thin, so diffusion occurs quickly. Also, the capillaries are so narrow that the red blood cells must pass through them in single file, which minimizes the diffusion distance from an alveolar air space to hemoglobin inside red blood cells. Buildup of interstitial fluid between alveoli, as occurs in pulmonary edema (page 914), slows the rate of gas exchange because it increases diffusion distance.

- **Molecular weight and solubility of the gases.** Because $O_2$ has a lower molecular weight than $CO_2$, it could be expected to diffuse across the respiratory membrane about 1.2 times faster. However, the solubility of $CO_2$ in the fluid portions of the respiratory membrane is about 24 times greater than that of $O_2$. Taking both of these factors into account, net outward $CO_2$ diffusion occurs 20 times more rapidly than net inward $O_2$ diffusion. Consequently, when diffusion is slower than normal, for example, in emphysema or pulmonary edema, $O_2$ insufficiency (hypoxia) typically occurs before there is significant retention of $CO_2$ (hypercapnia).

### Checkpoint
20. Distinguish between Dalton's law and Henry's law and give a practical application of each.
21. How does the partial pressure of oxygen change as altitude changes?
22. What are the diffusion paths of oxygen and carbon dioxide during external and internal respiration?
23. What factors affect the rate of diffusion of oxygen and carbon dioxide?
TRANSPORT OF OXYGEN AND CARBON DIOXIDE

OBJECTIVE
• Describe how the blood transports oxygen and carbon dioxide.

As you have already learned, the blood transports gases between the lungs and body tissues. When O₂ and CO₂ enter the blood, certain chemical reactions occur that aid in gas transport and gas exchange.

**Oxygen Transport**

Oxygen does not dissolve easily in water, so only about 1.5% of inhaled O₂ is dissolved in blood plasma, which is mostly water. About 98.5% of blood O₂ is bound to hemoglobin in red blood cells (Figure 23.18). Each 100 mL of oxygenated blood contains

**Figure 23.18** Transport of oxygen (O₂) and carbon dioxide (CO₂) in the blood.

Most O₂ is transported by hemoglobin as oxyhemoglobin (Hb–O₂) within red blood cells; most CO₂ is transported in blood plasma as bicarbonate ions (HCO₃⁻).

Transport of CO₂
- 7% dissolved in plasma
- 23% as Hb–CO₂
- 70% as HCO₃⁻

Transport of O₂
- 1.5% dissolved in plasma
- 98.5% as Hb–O₂

What is the most important factor that determines how much O₂ binds to hemoglobin?
the equivalent of 20 mL of gaseous O₂. Using the percentages just given, the amount dissolved in the plasma is 0.3 mL and the amount bound to hemoglobin is 19.7 mL.

The heme portion of hemoglobin contains four atoms of iron, each capable of binding to a molecule of O₂ (see Figure 19.4b, c on page 696). Oxygen and hemoglobin bind in an easily reversible reaction to form oxyhemoglobin:

\[ \text{Hb} + \text{O}_2 \rightarrow \text{Hb-O}_2 \]

The 98.5% of the O₂ that is bound to hemoglobin is trapped inside RBCs, so only the dissolved O₂ (1.5%) can diffuse out of tissue capillaries into tissue cells. Thus, it is important to understand the factors that promote O₂ binding to and dissociation (separation) from hemoglobin.

**The Relationship Between Hemoglobin and Oxygen Partial Pressure**

The most important factor that determines how much O₂ binds to hemoglobin is the P O₂; the higher the P O₂, the more O₂ combines with Hb. When reduced hemoglobin (Hb) is completely converted to oxyhemoglobin (Hb–O₂), the hemoglobin is said to be **fully saturated**; when hemoglobin consists of a mixture of Hb and Hb–O₂, it is **partially saturated**. The **percent saturation of hemoglobin** expresses the average saturation of hemoglobin with oxygen. For instance, if each hemoglobin molecule has bound two O₂ molecules, then the hemoglobin is 50% saturated because each Hb can bind a maximum of four O₂.

The relationship between the percent saturation of hemoglobin and P O₂ is illustrated in the oxygen–hemoglobin dissociation curve in Figure 23.19. Note that when the P O₂ is high, hemoglobin binds with large amounts of O₂ and is almost 100% saturated. When P O₂ is low, hemoglobin is only partially saturated. In other words, the greater the P O₂, the more O₂ will bind to hemoglobin, until all the available hemoglobin molecules are saturated. Therefore, in pulmonary capillaries, where P O₂ is high, a lot of O₂ binds to hemoglobin. In tissue capillaries, where the P O₂ is lower, hemoglobin does not hold as much O₂, and the dissolved O₂ is unloaded via diffusion into tissue cells (see Figure 23.18b). Note that hemoglobin is still 75% saturated with O₂ at a P O₂ of 40 mmHg, the average P O₂ of tissue cells in a person at rest. This is the basis for the earlier statement that only 25% of the available O₂ unloads from hemoglobin and is used by tissue cells under resting conditions.

When the P O₂ is between 60 and 100 mmHg, hemoglobin is 90% or more saturated with O₂ (Figure 23.19). Thus, blood picks up a nearly full load of O₂ from the lungs even when the P O₂ of alveolar air is as low as 60 mmHg. The Hb–P O₂ curve explains why people can still perform well at high altitudes or when they have certain cardiac and pulmonary diseases, even though P O₂ may drop as low as 60 mmHg. Note also in the curve that at a considerably lower P O₂ of 40 mmHg, hemoglobin is still 75% saturated with O₂. However, oxygen saturation of Hb drops to 35% at 20 mmHg. Between 40 and 20 mmHg, large amounts of O₂ are released from hemoglobin in response to only small decreases in P O₂. In active tissues such as contracting muscles, P O₂ may drop well below 40 mmHg. Then, a large percentage of the O₂ is released from hemoglobin, providing more O₂ to metabolically active tissues.

**Other Factors Affecting the Affinity of Hemoglobin for Oxygen**

Although P O₂ is the most important factor that determines the percent O₂ saturation of hemoglobin, several other factors influence the tightness or **affinity** with which hemoglobin binds O₂. In effect, these factors shift the entire curve either to the left (higher affinity) or to the right (lower affinity). The changing affinity of hemoglobin for O₂ is another example of how homeostatic mechanisms adjust body activities to cellular needs. Each one makes sense if you keep in mind that metabolically active tissue cells need O₂ and produce acids, CO₂, and heat as wastes. The following four factors affect the affinity of hemoglobin for O₂:

1. **Acidity (pH).** As acidity increases (pH decreases), the affinity of hemoglobin for O₂ decreases, and O₂ dissociates more readily from hemoglobin (Figure 23.20a). In other words, increasing acidity enhances the unloading of oxygen from hemoglobin. The main acids produced by metabolically active tissues are lactic acid and carbonic acid. When pH decreases, the entire

![Figure 23.19 Oxygen–hemoglobin dissociation curve showing the relationship between hemoglobin saturation and P O₂ at normal body temperature.](image_url)

As P O₂ increases, more O₂ combines with hemoglobin.

**What point on the curve represents blood in your pulmonary veins right now? In your pulmonary veins if you were jogging?**
**CHAPTER 23 • THE RESPIRATORY SYSTEM**

Oxygen–hemoglobin dissociation curve shifts to the right; at any given $P_{O_2}$, Hb is less saturated with $O_2$, a change termed the **Bohr effect**. The Bohr effect works both ways: An increase in $H^+$ in blood causes $O_2$ to unload from hemoglobin, and the binding of $O_2$ to hemoglobin causes unloading of $H^+$ from hemoglobin. The explanation for the Bohr effect is that hemoglobin can act as a buffer for hydrogen ions ($H^+$). But when $H^+$ ions bind to amino acids in hemoglobin, they alter its structure slightly, decreasing its oxygen-carrying capacity. Thus, lowered pH drives $O_2$ off hemoglobin, making more $O_2$ available for tissue cells. By contrast, elevated pH increases the affinity of hemoglobin for $O_2$ and shifts the oxygen–hemoglobin dissociation curve to the left.

2. **Partial pressure of carbon dioxide**. $CO_2$ also can bind to hemoglobin, and the effect is similar to that of $H^+$ (shifting the curve to the right). As $P_{CO_2}$ rises, hemoglobin releases $O_2$ more readily (Figure 23.20b). $P_{CO_2}$ and pH are related factors because low blood pH (acidity) results from high $P_{CO_2}$. As $CO_2$ enters the blood, much of it is temporarily converted to carbonic acid ($H_2CO_3$), a reaction catalyzed by an enzyme in red blood cells called **carbonic anhydrase (CA)**:

$$CO_2 + H_2O \underset{CA}{\leftrightarrow} H_2CO_3 \underset{H+}{\leftrightarrow} H^+ + HCO_3^-$$

The carbonic acid thus formed in red blood cells dissociates into hydrogen ions and bicarbonate ions. As the $H^+$ concentration increases, pH decreases. Thus, an increased $P_{CO_2}$ produces a more acidic environment, which helps release $O_2$ from hemoglobin. During exercise, lactic acid—a byproduct of anaerobic metabolism within muscles—also decreases blood pH. Decreased $P_{CO_2}$ (and elevated pH) shifts the saturation curve to the left.

3. **Temperature**. Within limits, as temperature increases, so does the amount of $O_2$ released from hemoglobin (Figure 23.21). Heat is a byproduct of the metabolic reactions of all cells, and the heat released by contracting muscle fibers tends to raise body temperature. Metabolically active cells require more $O_2$ and liberate more acids and heat. The acids and heat in turn promote release of $O_2$ from oxyhemoglobin. Fever produces a similar result. In contrast, during hypothermia (lowered body temperature) cellular metabolism slows, the need for $O_2$ is reduced, and more $O_2$ remains bound to hemoglobin (a shift to the left in the saturation curve).

4. **BPG**. A substance found in red blood cells called **2, 3-bisphosphoglycerate (BPG)**, previously called diphosphoglycerate (DPG), decreases the affinity of hemoglobin for $O_2$ and thus helps unload $O_2$ from hemoglobin. BPG is formed in red blood cells when they break down glucose to produce ATP in a process called glycolysis (described on page 980). When BPG combines with hemoglobin by binding to the terminal amino groups of the two beta globin chains, the hemoglobin binds $O_2$ less tightly at the heme group sites. The greater the level of BPG, the more $O_2$ is unloaded from hemoglobin. Certain hormones, such as thyroxine, human growth hormone, epinephrine, norepinephrine, and testosterone, increase the formation of BPG. The level of BPG also is higher in people living at higher altitudes.

**Figure 23.20** Oxygen–hemoglobin dissociation curves showing the relationship of (a) pH and (b) $P_{CO_2}$ to hemoglobin saturation at normal body temperature. As pH increases or $P_{CO_2}$ decreases, $O_2$ combines more tightly with hemoglobin, so that less is available to tissues. The broken lines emphasize these relationships.

In comparison to the value when you are sitting, is the affinity of your hemoglobin for $O_2$ higher or lower when you are exercising? How does this benefit you?
Figure 23.21  Oxygen–hemoglobin dissociation curves showing the effect of temperature changes.

As temperature increases, the affinity of hemoglobin for \( \text{O}_2 \) decreases.

Is \( \text{O}_2 \) more available or less available to tissue cells when you have a fever? Why?

**Oxygen Affinity of Fetal and Adult Hemoglobin**

Fetal hemoglobin (Hb-F) differs from adult hemoglobin (Hb-A) in structure and in its affinity for \( \text{O}_2 \). Hb-F has a higher affinity for \( \text{O}_2 \) because it binds BPG less strongly. Thus, when \( \text{PO}_2 \) is low, Hb-F can carry up to 30% more \( \text{O}_2 \) than maternal Hb-A (Figure 23.22). As the maternal blood enters the placenta, \( \text{O}_2 \) is readily transferred to fetal blood. This is very important because the \( \text{O}_2 \) saturation in maternal blood in the placenta is quite low, and the fetus might suffer hypoxia were it not for the greater affinity of fetal hemoglobin for \( \text{O}_2 \).

**Carbon Dioxide Transport**

Under normal resting conditions, each 100 mL of deoxygenated blood contains the equivalent of 53 mL of gaseous \( \text{CO}_2 \), which is transported in the blood in three main forms (see Figure 23.18):

1. **Dissolved CO**

   The smallest percentage—about 7%—is dissolved in blood plasma. Upon reaching the lungs, it diffuses into alveolar air and is exhaled.

2. **Carbamino compounds**

   A somewhat higher percentage, about 23%, combines with the amino groups of amino acids and proteins in blood to form carbamino compounds. Because the most prevalent protein in blood is hemoglobin (inside red blood cells), most of the \( \text{CO}_2 \) transported in this manner is bound to hemoglobin. The main \( \text{CO}_2 \) binding sites are the terminal amino acids in the two alpha and two beta globin chains. Hemoglobin that has bound \( \text{CO}_2 \) is termed carbaminohemoglobin (Hb–\( \text{CO}_2 \)):

   \[
   \text{Hb} + \text{CO}_2 \rightarrow \text{Hb–CO}_2
   \]

   The formation of carbaminohemoglobin is greatly influenced by \( \text{PCO}_2 \). For example, in tissue capillaries \( \text{PCO}_2 \) is relatively high, which promotes formation of carbaminohemoglobin. But in pulmonary capillaries, \( \text{PCO}_2 \) is relatively low, and the \( \text{CO}_2 \) readily splits apart from globin and enters the alveoli by diffusion.

Carbon monoxide (CO) is a colorless and odorless gas found in exhaust fumes from automobiles, gas furnaces, and space heaters and in tobacco smoke. It is a byproduct of the combustion of carbon-containing materials such as coal, gas, and wood. CO binds to the heme group of hemoglobin, just as \( \text{O}_2 \) does, except that the binding of carbon monoxide to hemoglobin is over 200 times as strong as the binding of \( \text{O}_2 \) to hemoglobin. Thus, at a concentration as small as 0.1% (\( \text{PCO}_2 = 0.5 \text{ mmHg} \)), CO will combine with half the available hemoglobin molecules and reduce the oxygen-carrying capacity of the blood by 50%. Elevated blood levels of CO cause carbon monoxide poisoning, which can cause the lips and oral mucosa to appear bright, cherry-red (the color of hemoglobin with carbon monoxide bound to it). Without prompt treatment, carbon monoxide poisoning is fatal. It is possible to rescue a victim of CO poisoning by administering pure oxygen, which speeds up the separation of carbon monoxide from hemoglobin.

Is \( \text{O}_2 \) more available or less available to tissue cells when you have a fever? Why?

**CLINICAL CONNECTION** Carbon Monoxide Poisoning

The \( \text{PO}_2 \) of placental blood is about 40 mmHg. What are the \( \text{O}_2 \) saturations of maternal and fetal hemoglobin at this \( \text{PO}_2 \)?
3. **Bicarbonate ions.** The greatest percentage of CO₂—about 70%—is transported in blood plasma as **bicarbonate ions** (HCO₃⁻). As CO₂ diffuses into systemic capillaries and enters red blood cells, it reacts with water in the presence of the enzyme carbonic anhydrase (CA) to form carbonic acid, which dissociates into H⁺ and HCO₃⁻:

\[
\text{CO}_2 + \text{H}_2\text{O} \xrightarrow{\text{CA}} \text{H}_2\text{CO}_3 \xrightarrow{} \text{H}^+ + \text{HCO}_3^-
\]

Thus, as blood picks up CO₂, HCO₃⁻ accumulates inside RBCs. Some HCO₃⁻ moves out into the blood plasma, down its concentration gradient. In exchange, chloride ions (Cl⁻) move from plasma into the RBCs. This exchange of negative ions, which maintains the electrical balance between blood plasma and RBC cytosol, is known as the **chloride shift** (Figure 23.23b). The net effect of these reactions is that CO₂ is removed from tissue cells and transported in blood plasma as HCO₃⁻. As blood passes through pulmonary capillaries in the lungs, all these reactions reverse and CO₂ is exhaled.

**Figure 23.23** Summary of chemical reactions that occur during gas exchange. (a) As carbon dioxide (CO₂) is exhaled, hemoglobin (Hb) inside red blood cells in pulmonary capillaries unloads CO₂ and picks up O₂ from alveolar air. Binding of O₂ to Hb—H releases hydrogen ions (H⁺). Bicarbonate ions (HCO₃⁻) pass into the RBC and bind to released H⁺, forming carbonic acid (H₂CO₃). The H₂CO₃ dissociates into water (H₂O) and CO₂, and the CO₂ diffuses from blood into alveolar air. To maintain electrical balance, a chloride ion (Cl⁻) exits the RBC for each HCO₃⁻ that enters (reverse chloride shift). (b) CO₂ diffuses out of tissue cells that produce it and enters red blood cells, where some of it binds to hemoglobin, forming carbaminohemoglobin (Hb–CO₂). This reaction causes O₂ to dissociate from oxyhemoglobin (Hb–O₂). Other molecules of CO₂ combine with water to produce bicarbonate ions (HCO₃⁻) and hydrogen ions (H⁺). As Hb buffers H⁺, the Hb releases O₂ (Bohr effect). To maintain electrical balance, a chloride ion (Cl⁻) enters the RBC for each HCO₃⁻ that exits (chloride shift).

Hemoglobin inside red blood cells transports O₂, CO₂, and H⁺.

Would you expect the concentration of HCO₃⁻ to be higher in blood plasma taken from a systemic artery or a systemic vein?
The amount of CO₂ that can be transported in the blood is influenced by the percent saturation of hemoglobin with oxygen. The lower the amount of oxyhemoglobin (Hb–O₂), the higher the CO₂ carrying capacity of the blood, a relationship known as the Haldane effect. Two characteristics of deoxyhemoglobin give rise to the Haldane effect: (1) Deoxyhemoglobin binds to and thus transports more CO₂ than does Hb–O₂. (2) Deoxyhemoglobin also buffers more H⁺ than does Hb–O₂, thereby removing H⁺ from solution and promoting conversion of CO₂ to HCO₃⁻ via the reaction catalyzed by carbonic anhydrase.

Summary of Gas Exchange and Transport in Lungs and Tissues

Deoxygenated blood returning to the pulmonary capillaries in the lungs (Figure 23.23a on page 904) contains CO₂ dissolved in blood plasma, CO₂ combined with globin as carbaminohemoglobin (Hb–CO₂), and CO₂ incorporated into HCO₃⁻ within RBCs. The RBCs have also picked up H⁺, some of which binds to and therefore is buffered by hemoglobin (Hb–H). As blood passes through the pulmonary capillaries, molecules of CO₂ dissolved in blood plasma and CO₂ that dissociates from the globin portion of hemoglobin diffuse into alveolar air and are exhaled. At the same time, inhaled O₂ is diffusing from alveolar air into RBCs and is binding to hemoglobin to form oxyhemoglobin (Hb–O₂). Carbon dioxide also is released from HCO₃⁻ when H⁺ combines with HCO₃⁻ inside RBCs. The H₂CO₃ formed from this reaction then splits into CO₂, which is exhaled, and H₂O. As the concentration of HCO₃⁻ declines inside RBCs in pulmonary capillaries, HCO₃⁻ diffuses in from the blood plasma, in exchange for Cl⁻. In sum, oxygenated blood leaving the lungs has increased O₂ content and decreased amounts of CO₂ and H⁺. In systemic capillaries, as cells use O₂ and produce CO₂, the chemical reactions reverse (Figure 23.23b).

CHECKPOINT

24. In a resting person, how many O₂ molecules are attached to each hemoglobin molecule, on average, in blood in the pulmonary arteries? In blood in the pulmonary veins?
25. What is the relationship between hemoglobin and PₐO₂? How do temperature, H⁺, PₐCO₂, and BPG influence the affinity of Hb for O₂?
26. Why can hemoglobin unload more oxygen as blood flows through capillaries of metabolically active tissues, such as skeletal muscle during exercise, than is unloaded at rest?

CONTROL OF RESPIRATION

OBJECTIVES

• Explain how the nervous system controls breathing.
• List the factors that can alter the rate and depth of breathing.

At rest, about 200 mL of O₂ are used each minute by body cells. During strenuous exercise, however, O₂ use typically increases 15- to 20-fold in normal healthy adults, and as much as 30-fold in elite endurance-trained athletes. Several mechanisms help match respiratory effort to metabolic demand.

Respiratory Center

The size of the thorax is altered by the action of the respiratory muscles, which contract as a result of nerve impulses transmitted to them from centers in the brain and relax in the absence of nerve impulses. These nerve impulses are sent from clusters of neurons located bilaterally in the medulla oblongata and pons of the brain stem. This widely dispersed group of neurons, collectively called the respiratory center, can be divided into three areas on the basis of their functions: (1) the medullary rhythmicity area in the medulla oblongata; (2) the pneumotaxic area in the pons; and (3) the apneustic area, also in the pons (Figure 23.24).

Medullary Rhythmicity Area

The function of the medullary rhythmicity area (rith-MIS-i-té) is to control the basic rhythm of respiration. There are inspiratory and expiratory areas within the medullary rhythmicity
area. Figure 23.25 shows the relationships of the inspiratory and expiratory areas during normal quiet breathing and forceful breathing.

During quiet breathing, inhalation lasts for about 2 seconds and exhalation lasts for about 3 seconds. Nerve impulses generated in the inspiratory area establish the basic rhythm of breathing. While the inspiratory area is active, it generates nerve impulses for about 2 seconds (Figure 23.25a). The impulses propagate to the external intercostal muscles via intercostal nerves and to the diaphragm via the phrenic nerves. When the nerve impulses reach the diaphragm and external intercostal muscles, the muscles contract and inhalation occurs. Even when all incoming nerve connections to the inspiratory area are cut or blocked, neurons in this area still rhythmically discharge impulses that cause inhalation. At the end of 2 seconds, the inspiratory area becomes inactive and nerve impulses cease. With no impulses arriving, the diaphragm and external intercostal muscles relax for about 3 seconds, allowing passive elastic recoil of the lungs and thoracic wall. Then, the cycle repeats.

The neurons of the expiratory area remain inactive during quiet breathing. However, during forceful breathing nerve impulses from the inspiratory area activate the expiratory area (Figure 23.25b). Impulses from the expiratory area cause contraction of the internal intercostal and abdominal muscles, which decreases the size of the thoracic cavity and causes forceful exhalation.

**Pneumotaxic Area**

Although the medullary rhythmicity area controls the basic rhythm of respiration, other sites in the brain stem help coordinate the transition between inhalation and exhalation. One of these sites is the pneumotaxic area (pneumo- = air or breath; -taxic = arrangement) in the upper pons (see Figure 23.24), which transmits inhibitory impulses to the inspiratory area. The major effect of these nerve impulses is to help turn off the inspiratory area before the lungs become too full of air. In other words, the impulses shorten the duration of inhalation. When the pneumotaxic area is more active, breathing rate is more rapid.

**Apneustic Area**

Another part of the brain stem that coordinates the transition between inhalation and exhalation is the apneustic area (ap-NOO-stik) in the lower pons (see Figure 23.24). This area sends stimulatory impulses to the inspiratory area that activate it and prolong inhalation. The result is a long, deep inhalation. When the pneumotaxic area is active, it overrides signals from the apneustic area.

**Regulation of the Respiratory Center**

The basic rhythm of respiration set and coordinated by the inspiratory area can be modified in response to inputs from other brain regions, receptors in the peripheral nervous system, and other factors.

**Cortical Influences on Respiration**

Because the cerebral cortex has connections with the respiratory center, we can voluntarily alter our pattern of breathing. We can even refuse to breathe at all for a short time. Voluntary control is protective because it enables us to prevent water or irritating

---

**Figure 23.25** Roles of the medullary rhythmicity area in controlling (a) the basic rhythm of respiration and (b) forceful breathing.

During normal, quiet breathing, the expiratory area is inactive; during forceful breathing, the inspiratory area activates the expiratory area.

Which nerves convey impulses from the respiratory center to the diaphragm?
gases from entering the lungs. The ability to not breathe, however, is limited by the buildup of CO₂ and H⁺ in the body. When PCO₂ and H⁺ concentrations increase to a certain level, the inspiratory area is strongly stimulated, nerve impulses are sent along the phrenic and intercostal nerves to inspiratory muscles, and breathing resumes, whether the person wants it to or not. It is impossible for small children to kill themselves by voluntarily holding their breath, even though many have tried in order to get their way. If breath is held long enough to cause fainting, breathing resumes when consciousness is lost. Nerve impulses from the hypothalamus and limbic system also stimulate the respiratory center, allowing emotional stimuli to alter respirations as, for example, in laughing and crying.

**Chemoreceptor Regulation of Respiration**

Certain chemical stimuli modulate how quickly and how deeply we breathe. The respiratory system functions to maintain proper levels of CO₂ and O₂ and is very responsive to changes in the levels of these gases in body fluids. We introduced sensory neurons that are responsive to chemicals, called chemoreceptors, in Chapter 21. Chemoreceptors in two locations monitor levels of CO₂, H⁺, and O₂ and provide input to the respiratory center (Figure 23.26). **Central chemoreceptors** are located in or near the medulla oblongata in the central nervous system. They respond to changes in H⁺ concentration or PCO₂, or both, in cerebrospinal fluid. **Peripheral chemoreceptors** are located in the aortic bodies, clusters of chemoreceptors located in the wall of the arch of the aorta, and in the carotid bodies, which are oval nodules in the wall of the left and right common carotid arteries where they divide into the internal and external carotid arteries. (The chemoreceptors of the aortic bodies are located close to the aortic baroreceptors, and the carotid bodies are located close to the carotid sinus baroreceptors. Recall from Chapter 21 that baroreceptors are sensory receptors that monitor blood pressure.) These chemoreceptors are part of the peripheral nervous system and are sensitive to changes in PO₂, H⁺, and PCO₂ in the blood. Axons of sensory neurons from the aortic bodies are part of the vagus (X) nerves, and those from the carotid bodies are part of the right and left glosopharyngeal (IX) nerves.

Because CO₂ is lipid-soluble, it easily diffuses into cells where in the presence of carbonic anhydrase, it combines with water, (H₂O) to form carbonic acid (H₂CO₃). Carbonic acid quickly breaks down into H⁺ and HCO₃⁻. Thus, an increase in CO₂ in the blood causes an increase in H⁺ inside cells, and a decrease in CO₂ causes a decrease in H⁺.

Normally, the PCO₂ in arterial blood is 40 mmHg. If even a slight increase in PCO₂ occurs—a condition called hypercapnia or hypercarbia—the central chemoreceptors are stimulated and respond vigorously to the resulting increase in H⁺ level. The peripheral chemoreceptors also are stimulated by both the high PCO₂ and the rise in H⁺. In addition, the peripheral chemoreceptors (but not the central chemoreceptors) respond to a deficiency of O₂. When PO₂ in arterial blood falls from a normal level of
100 mmHg but is still above 50 mmHg, the peripheral chemoreceptors are stimulated. Severe deficiency of O₂ depresses activity of the central chemoreceptors and inspiratory area, which then do not respond well to any inputs and send fewer impulses to the muscles of inhalation. As the breathing rate decreases or breathing ceases altogether, P O₂ falls lower and lower, establishing a positive feedback cycle with a possibly fatal result.

The chemoreceptors participate in a negative feedback system that regulates the levels of CO₂, O₂, and H⁺ in the blood (Figure 23.27). As a result of increased P CO₂, decreased pH (increased H⁺), or decreased P O₂, input from the central and peripheral chemoreceptors causes the inspiratory area to become highly active, and the rate and depth of breathing increase. Rapid and deep breathing, called hyperventilation, allows the inhalation of more O₂ and exhalation of more CO₂ until P CO₂ and H⁺ are lowered to normal.

If arterial P CO₂ is lower than 40 mmHg—a condition called hypocapnia or hypocarbia—the central and peripheral chemoreceptors are not stimulated, and stimulatory impulses are not sent to the inspiratory area. As a result, the area sets its own moderate pace until CO₂ accumulates and the P CO₂ rises to 40 mmHg. The inspiratory center is more strongly stimulated when P CO₂ is rising above normal than when P O₂ is falling below normal. As a result, people who hyperventilate voluntarily and cause hypocapnia can hold their breath for an unusually long period. Swimmers were once encouraged to hyperventilate just before diving in to compete. However, this practice is risky because the O₂ level may fall dangerously low and cause fainting before the P CO₂ rises high enough to stimulate inhalation. If you faint on land you may suffer bumps and bruises, but if you faint in the water you could drown.

**CLINICAL CONNECTION Hypoxia**

Hypoxia (hi-POK-se-a; hypo- = under) is a deficiency of O₂ at the tissue level. Based on the cause, we can classify hypoxia into four types, as follows:

1. **Hypoxic hypoxia** is caused by a low P O₂ in arterial blood as a result of high altitude, airway obstruction, or fluid in the lungs.
2. In anemic hypoxia, too little functioning hemoglobin is present in the blood, which reduces O₂ transport to tissue cells. Among the causes are hemorrhage, anemia, and failure of hemoglobin to carry its normal complement of O₂, as in carbon monoxide poisoning.
3. In ischemic hypoxia, blood flow to a tissue is so reduced that too little O₂ is delivered to it, even though P O₂ and oxyhemoglobin levels are normal.
4. In histotoxic hypoxia, the blood delivers adequate O₂ to tissues, but the tissues are unable to use it properly because of the action of some toxic agent. One cause is cyanide poisoning, in which cyanide blocks an enzyme required for the use of O₂ during ATP synthesis.

**Figure 23.27** Regulation of breathing in response to changes in blood P CO₂, P O₂, and pH (H⁺ concentration) via negative feedback control.

What is the normal arterial blood P CO₂?
Proprioceptor Stimulation of Respiration

As soon as you start exercising, your rate and depth of breathing increase, even before changes in \( P_{O_2} \), \( P_{CO_2} \), or \( H^+ \) level occur. The main stimulus for these quick changes in respiratory effort is input from proprioceptors, which monitor movement of joints and muscles. Nerve impulses from the proprioceptors stimulate the inspiratory area of the medulla oblongata. At the same time, axon collaterals (branches) of upper motor neurons that originate in the primary motor cortex (precentral gyrus) also feed excitatory impulses into the inspiratory area.

The Inflation Reflex

Similar to those in the blood vessels, stretch-sensitive receptors called baroreceptors or stretch receptors are located in the walls of bronchi and bronchioles. When these receptors become stretched during overinflation of the lungs, nerve impulses are sent along the vagus (X) nerves to the inspiratory and apneustic areas. In response, the inspiratory area is inhibited directly, and the apneustic area is inhibited from activating the inspiratory area. As a result, exhalation begins. As air leaves the lungs during exhalation, the lungs deflate and the stretch receptors are no longer stimulated. Thus, the inspiratory and apneustic areas are no longer inhibited, and a new inhalation begins. This reflex, referred to as the inflation (Hering–Breuer) reflex, is mainly a protective mechanism for preventing excessive inflation of the lungs rather than a key component in the normal regulation of respiration.

Other Influences on Respiration

Other factors that contribute to regulation of respiration include the following:

- **Limbic system stimulation.** Anticipation of activity or emotional anxiety may stimulate the limbic system, which then sends excitatory input to the inspiratory area, increasing the rate and depth of ventilation.
- **Temperature.** An increase in body temperature, as occurs during a fever or vigorous muscular exercise, increases the rate of respiration. A decrease in body temperature decreases respiratory rate. A sudden cold stimulus (such as plunging into cold water) causes temporary apnea (AP-nē-ə; \( a- \) = without; -pnea = breath), an absence of breathing.
- **Pain.** A sudden, severe pain brings about brief apnea, but a prolonged somatic pain increases respiratory rate. Visceral pain may slow the rate of respiration.
- **Stretching the anal sphincter muscle.** This action increases the respiratory rate and is sometimes used to stimulate respiration in a newborn baby or a person who has stopped breathing.
- **Irritation of airways.** Physical or chemical irritation of the pharynx or larynx brings about an immediate cessation of breathing followed by coughing or sneezing.
- **Blood pressure.** The carotid and aortic baroreceptors that detect changes in blood pressure have a small effect on respiration. A sudden rise in blood pressure decreases the rate of respiration, and a drop in blood pressure increases the respiratory rate.

Table 23.2 summarizes the stimuli that affect the rate and depth of ventilation.

<table>
<thead>
<tr>
<th>TABLE 23.2 Summary of Stimuli That Affect Ventilation Rate and Depth</th>
</tr>
</thead>
</table>

**STIMULI THAT INCREASE VENTILATION RATE AND DEPTH**

- Voluntary hyperventilation controlled by the cerebral cortex and anticipation of activity by stimulation of the limbic system.
- Increase in arterial blood \( P_{CO_2} \) above 40 mmHg (causes an increase in \( H^+ \)) detected by peripheral and central chemoreceptors.
- Decrease in arterial blood \( P_{O_2} \) from 105 mmHg to 50 mmHg.
- Increased activity of proprioreceptors.
- Increase in body temperature.
- Prolonged pain.
- Decrease in blood pressure.
- Stretching the anal sphincter.

**STIMULI THAT DECREASE VENTILATION RATE AND DEPTH**

- Voluntary hypoventilation controlled by the cerebral cortex.
- Decrease in arterial blood \( P_{CO_2} \) below 40 mmHg (causes a decrease in \( H^+ \)) detected by peripheral and central chemoreceptors.
- Decrease in arterial blood \( P_{O_2} \) below 50 mmHg.
- Decreased activity of proprioreceptors.
- Decrease in body temperature decreases the rate of respiration, and a sudden cold stimulus causes apnea.
- Severe pain causes apnea.
- Increase in blood pressure.
- Irritation of pharynx or larynx by touch or chemicals causes brief apnea followed by coughing or sneezing.
EXERCISE AND THE RESPIRATORY SYSTEM

**OBJECTIVE**
- Describe the effects of exercise on the respiratory system.

The respiratory and cardiovascular systems make adjustments in response to both the intensity and duration of exercise. The effects of exercise on the heart are discussed in Chapter 20. Here we focus on how exercise affects the respiratory system.

Recall that the heart pumps the same amount of blood to the lungs as to all the rest of the body. Thus, as cardiac output rises, the blood flow to the lungs, termed *pulmonary perfusion*, increases as well. In addition, the *O₂ diffusing capacity*, a measure of the rate at which O₂ can diffuse from alveolar air into the blood, may increase threefold during maximal exercise because more pulmonary capillaries become maximally perfused. As a result, there is a greater surface area available for diffusion of O₂ into pulmonary blood capillaries.

When muscles contract during exercise, they consume large amounts of O₂ and produce large amounts of CO₂. During vigorous exercise, O₂ consumption and pulmonary ventilation both increase dramatically. At the onset of exercise, an abrupt increase in pulmonary ventilation is followed by a more gradual increase. With moderate exercise, the increase is due mostly to an increase in the depth of ventilation rather than to increased breathing rate. When exercise is more strenuous, the frequency of breathing also increases.

The abrupt increase in ventilation at the start of exercise is due to *neural* changes that send excitatory impulses to the inspiratory area in the medulla oblongata. These changes include (1) anticipation of the activity, which stimulates the limbic system; (2) sensory impulses from proprioceptors in muscles, tendons, and joints; and (3) motor impulses from the primary motor cortex (precentral gyrus). The more gradual increase in ventilation during moderate exercise is due to *chemical* and *physical* changes in the bloodstream, including (1) slightly decreased P\textsubscript{O₂} due to increased O₂ consumption; (2) slightly increased P\textsubscript{CO₂} due to increased CO₂ production by contracting muscle fibers; and (3) increased temperature, due to liberation of more heat as more O₂ is utilized. During strenuous exercise, HCO\textsuperscript{3-} buffers H\textsuperscript{+} released by lactic acid in a reaction that liberates CO₂, which further increases P\textsubscript{CO₂}.

At the end of an exercise session, an abrupt decrease in pulmonary ventilation is followed by a more gradual decline to the resting level. The initial decrease is due mainly to changes in neural factors when movement stops or slows; the more gradual phase reflects the slower return of blood chemistry levels and temperature to the resting state.

**CLINICAL CONNECTION**  The Effect of Smoking on Respiratory Efficiency

Smoking may cause a person to become easily “winded” during even moderate exercise because several factors decrease respiratory efficiency in smokers: (1) Nicotine constricts terminal bronchioles, which decreases airflow into and out of the lungs. (2) Carbon monoxide in smoke binds to hemoglobin and reduces its oxygen-carrying capability. (3) Irritants in smoke cause increased mucus secretion by the mucosa of the bronchial tree and swelling of the mucosal lining, both of which impede airflow into and out of the lungs. (4) Irritants in smoke also inhibit the movement of cilia and destroy cilia in the lining of the respiratory system. Thus, excess mucus and foreign debris are not easily removed, which further adds to the difficulty in breathing. (5) With time, smoking leads to destruction of elastic fibers in the lungs and is the prime cause of emphysema (described on page 913). These changes cause collapse of small bronchioles and trapping of air in alveoli at the end of exhalation. The result is less efficient gas exchange.

**CHECKPOINT**
30. How does exercise affect the inspiratory area?

DEVELOPMENT OF THE RESPIRATORY SYSTEM

**OBJECTIVE**
- Describe the development of the respiratory system.

The development of the mouth and pharynx are discussed in Chapter 24. Here we consider the development of the other structures of the respiratory system that you learned about in this chapter.

At about four weeks of development, the respiratory system begins as an outgrowth of the foregut (precursor of some digestive organs) just anterior to the pharynx. This outgrowth is called the **respiratory diverticulum** or **lung bud** (Figure 23.28). The **endoderm** lining the respiratory diverticulum gives rise to the epithelium and glands of the trachea, bronchi, and alveoli. **Mesoderm** surrounding the respiratory diverticulum gives rise to the connective tissue, cartilage, and smooth muscle of these structures.

The epithelial lining of the **larynx** develops from the **endoderm** of the respiratory diverticulum; the cartilages and muscles originate from the fourth and sixth pharyngeal arches, swellings on the surface of the embryo.

As the respiratory diverticulum elongates, its distal end enlarges to form a globular **tracheal bud**, which gives rise to the **trachea**. Soon after, the tracheal bud divides into **bronchial buds**, which branch repeatedly and develop with the **bronchi**. By 24 weeks, 17 orders of branches have formed and **respiratory bronchioles** have developed.

During weeks 6 to 16, all major elements of the **lungs** have formed, except for those involved in gaseous exchange (respiratory bronchioles, alveolar ducts, and alveoli). Since respiration is not possible at this stage, fetuses born during this time cannot survive.

During weeks 16 to 26, lung tissue becomes highly vascular and respiratory bronchioles, alveolar ducts, and some primitive alveoli develop. Although it is possible for a fetus born near the end of this period to survive if given intensive care, death
The respiratory system develops from endoderm and mesoderm. The respiratory system develops from endoderm and mesoderm.

When does the respiratory system begin to develop in an embryo?

frequently occurs due to the immaturity of the respiratory and other systems.

From 26 weeks to birth, many more primitive alveoli develop; they consist of type I alveolar cells (main sites of gaseous exchange) and type II surfactant-producing cells. Blood capillaries also establish close contact with the primitive alveoli. Recall that surfactant is necessary to lower surface tension of alveolar fluid and thus reduce the tendency of alveoli to collapse on exhalation. Although surfactant production begins by 20 weeks, it is present in only small quantities. Amounts sufficient to permit survival of a premature (preterm) infant are not produced until 26 to 28 weeks gestation. Infants born before 26 to 28 weeks are at high risk of respiratory distress syndrome (RDS), in which the alveoli collapse during exhalation and must be reinflated during inhalation (see page 894).

At about 30 weeks, mature alveoli develop. However, it is estimated that only about one-sixth of the full complement of alveoli develop before birth; the remainder develop after birth during the first eight years.

As the lungs develop, they acquire their pleural sacs. The visceral pleura and the parietal pleura develop from mesoderm. The space between the pleural layers is the pleural cavity.

During development, breathing movements of the fetus cause the aspiration of fluid into the lungs. This fluid is a mixture of amniotic fluid, mucus from bronchial glands, and surfactant. At birth, the lungs are about half-filled with fluid. When breathing begins at birth, most of the fluid is rapidly reabsorbed by blood and lymph capillaries and a small amount is expelled through the nose and mouth during delivery.

**CHECKPOINT**

31. What structures develop from the laryngotracheal bud?

**AGING AND THE RESPIRATORY SYSTEM**

**OBJECTIVE**

- Describe the effects of aging on the respiratory system.

With advancing age, the airways and tissues of the respiratory tract, including the alveoli, become less elastic and more rigid; the chest wall becomes more rigid as well. The result is a decrease in lung capacity. In fact, vital capacity (the maximum amount of air that can be expired after maximal inhalation) can decrease as much as 35% by age 70. A decrease in blood level of O₂, decreased activity of alveolar macrophages, and diminished ciliary action of the epithelium lining the respiratory tract occur. Because of these age-related factors, elderly people are more susceptible to pneumonia, bronchitis, emphysema, and other pulmonary disorders. Age-related changes in the structure and functions of the lung can also contribute to an older person’s reduced ability to perform vigorous exercises, such as running.

**CHECKPOINT**

32. What accounts for the decrease in lung capacity with aging?

To appreciate the many ways that the respiratory system contributes to homeostasis of other body systems, examine Focus on Homeostasis: The Respiratory System. Next, in Chapter 24, we will see how the digestive system makes nutrients available to body cells so that oxygen provided by the respiratory system can be used for ATP production.

Asthma

Asthma (AZ-ma = panting) is a disorder characterized by chronic airway inflammation, airflow obstruction, and hyperreactivity to a variety of stimuli and airway obstruction. It is at least partially reversible, either spontaneously or with treatment. Asthma affects 3-5% of the U.S. population and is more common in children than in adults. Airway obstruction may be due to smooth muscle spasms in the walls of smaller bronchi and bronchioles, edema of the mucosa of the airways, increased mucus secretion, and/or damage to the epithelium of the airway.

Individuals with asthma typically react to concentrations of agents too low to cause symptoms in people without asthma. Sometimes the trigger is an allergen such as pollen, house dust mites, molds, or a particular food. Other common triggers of asthma attacks are emotional upset, aspirin, sulfiting agents (used in wine and beer and to keep greens fresh in salad bars), exercise, and breathing cold air or cigarette smoke. In the early phase (acute) response, smooth muscle spasm is accompanied by excessive secretion of mucus that may clog the bronchi and bronchioles and worsen the attack. The late phase (chronic) response is characterized by inflammation, fibrosis, edema, and necrosis (death) of bronchial epithelial cells. A host of mediator chemicals, including leukotrienes, prostaglandins, thromboxane, platelet-activating factor, and histamine, take part.

Symptoms include difficult breathing, coughing, wheezing, chest tightness, tachycardia, fatigue, moist skin, and anxiety. An acute attack is treated by giving an inhaled beta₂-adrenergic agonist (albuterol) to help relax smooth muscle in the bronchioles and open up the airways. However, long-term therapy of asthma strives to suppress the underlying inflammation. The anti-inflammatory drugs that are used most often are inhaled corticosteroids (glucocorticoids), cromolyn sodium (Intal®), and leukotriene blockers (Accolate®).

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is a type of respiratory disorder characterized by chronic and recurrent obstruction of airflow, which increases airway resistance. COPD affects about 30 million Americans and is the fourth leading cause of death behind heart disease, cancer, and cerebrovascular disease. The principal types of COPD are emphysema and chronic bronchitis. In most cases, COPD is preventable because its most common cause is cigarette smoking or breathing secondhand smoke. Other causes include air pollution, pulmonary infection, occupational exposure to dusts and gases, and genetic factors. Because men, on average, have more years of exposure to cigarette smoke than women, they are twice as likely as women to suffer from COPD; still, the incidence of COPD in women has risen sixfold in the past 50 years, a reflection of increased smoking among women.

Emphysema

Emphysema (em-fi-SE-ma = blown up or full of air) is a disorder characterized by destruction of the walls of the alveoli, producing abnormally large air spaces that remain filled with air during exhalation. With less surface area for gas exchange, O₂ diffusion across the damaged respiratory membrane is reduced. Blood O₂ level is somewhat lowered, and any mild exercise that raises the O₂ requirements of the cells leaves the patient breathless. As increasing numbers of alveolar walls are damaged, lung elastic recoil decreases due to loss of elastic fibers, and an increasing amount of air becomes trapped in the lungs at the end of exhalation. Over several years, added exer-
CHAPTER 23

THE RESPIRATORY SYSTEM

jaundice. For some people, there are relatively few or no dramatic symptoms.

Treatment consists of partial or complete surgical removal of a diseased lung (pulmonectomy), radiation therapy, and chemotherapy.

Pneumonia

Pneumonia is an acute infection or inflammation of the alveoli. It is the most common infectious cause of death in the United States, where an estimated 4 million cases occur annually. When certain microbes enter the lungs of susceptible individuals, they release damaging toxins, stimulating inflammation and immune responses that have damaging side effects. The toxins and immune response damage alveoli and bronchial mucous membranes; inflammation and edema cause the alveoli to fill with fluid, interfering with ventilation and gas exchange.

The most common cause of pneumonia is the pneumococcal bacterium Streptococcus pneumoniae, but other microbes may also cause pneumonia. Those who are most susceptible to pneumonia are the elderly, infants, immunocompromised individuals (AIDS or cancer patients, or those taking immunosuppressive drugs), cigarette smokers, and individuals with an obstructive lung disease. Most cases of pneumonia are preceded by an upper respiratory infection that often is viral. Individuals then develop fever, chills, productive or dry cough, malaise, chest pain, and sometimes dyspnea (difficult breathing) and hemoptysis (spitting blood).

Treatment may involve antibiotics, bronchodilators, oxygen therapy, increased fluid intake, and chest physiotherapy (percussion, vibration, and postural drainage).

Tuberculosis

The bacterium Mycobacterium tuberculosis produces an infectious, communicable disease called tuberculosis (TB) that most often affects the lungs and the pleurae but may involve other parts of the body. Once the bacteria are inside the lungs, they multiply and cause inflammation, which stimulates neutrophils and macrophages to migrate to the area and engulf the bacteria to prevent their spread. If the immune system is not impaired, the bacteria remain dormant for life, but impaired immunity may enable the bacteria to escape into blood and lymph to infect other organs. In many people, symptoms—fatigue, weight loss, lethargy, anorexia, a low-grade fever, night sweats, cough, dyspnea, chest pain, and hemoptysis—do not develop until the disease is advanced.

During the past several years, the incidence of TB in the United States has risen dramatically. Perhaps the single most important factor related to this increase is the spread of the human immunodeficiency virus (HIV). People infected with HIV are much more likely to develop tuberculosis because their immune systems are impaired. Among the other factors that have contributed to the increased number of cases are homelessness, increased drug abuse, increased immigration from countries with a high prevalence of tuberculosis, increased crowding in housing among the poor, and airborne transmission of tuberculosis in prisons and shelters. In addition, recent outbreaks of tuberculosis involving multi-drug-resistant strains of Mycobacterium tuberculosis have occurred because patients fail to complete their antibiotic and other treatment regimens. TB is treated with the medication isoniazid.

Coryza and Influenza

Hundreds of viruses can cause coryza (ko-RI-Za) or the common cold, but a group of viruses called rhinoviruses is responsible for about 40% of all colds in adults. Typical symptoms include sneezing, exsive nasal secretion, dry cough, and congestion. The uncomplicated common cold is not usually accompanied by a fever. Complications include sinusitis, asthma, bronchitis, ear infections, and laryngitis. Recent investigations suggest an association between emotional stress and the common cold. The higher the stress level, the greater the frequency and duration of colds.

Influenza (flu) is also caused by a virus. Its symptoms include chills, fever (usually higher than 101°F = 39°C), headache, and muscular aches. Influenza can become life-threatening and may develop into pneumonia. It is important to recognize that influenza is a respiratory disease, not a gastrointestinal (GI) disease. Many people mistakenly report having "the flu" when they are suffering from a GI illness.

Pulmonary Edema

Pulmonary edema is an abnormal accumulation of fluid in the interstitial spaces and alveoli of the lungs. The edema may arise from increased permeability of the pulmonary capillaries (pulmonary origin) or increased pressure in the pulmonary capillaries (cardiac origin); the latter cause may coincide with congestive heart failure. The most common symptom is dyspnea. Others include wheezing, tachypnea (rapid breathing rate), restlessness, a feeling of suffocation, cyanosis, pallor (paleness), diaphoresis (excessive perspiration), and pulmonary hypertension. Treatment consists of administering oxygen, drugs that dilate the bronchioles and lower blood pressure, diuretics to rid the body of excess fluid, and drugs that correct acid-base imbalance; suctioning of airways; and mechanical ventilation. One of the recent culprits in the development of pulmonary edema was found to be "phen-fen" diet pills.

Cystic Fibrosis

Cystic fibrosis (CF) is an inherited disease of secretory epithelia that affects the airways, liver, pancreas, small intestine, and sweat glands. It is the most common lethal genetic disease in whites: 5% of the population are thought to be genetic carriers. The cause of cystic fibrosis is a genetic mutation affecting a transporter protein that carries chloride ions across the plasma membranes of many epithelial cells. Because dysfunction of sweat glands causes perspiration to contain excessive sodium chloride (salt), measurement of the excess chloride is one index for diagnosing CF. The mutation also disrupts the normal functioning of several organs by causing ducts within them to become obstructed by thick mucus secretions that do not drain easily from the passageways. Buildup of these secretions leads to inflammation and replacement of injured cells with connective tissue that further blocks the ducts. Clogging and infection of the airways leads to difficulty in breathing and eventual destruction of lung tissue. Lung disease accounts for most deaths from CF. Obstruction of small bile ducts in the liver interferes with digestion and disrupts liver function; clogging of pancreatic ducts prevents digestive enzymes from reaching the small intestine. Because pancreatic juice contains the main fat-digesting enzyme, the person fails to absorb fats or fat-soluble vitamins and thus suffers from vitamin A, D, and K deficiency diseases. With respect to the reproductive systems, blockage of the ductus (vas) deferens leads to infertility in males; the formation of dense mucus plugs in the vagina restricts the entry of sperm into the uterus and can lead to infertility in females.

A child suffering from cystic fibrosis is given pancreatic extract and large doses of vitamins A, D, and K. The recommended diet is high in calories, fats, and proteins, with vitamin supplementation and liberal use of salt. One of the newest treatments for CF is heart-lung transplants.
Asbestos-related Diseases
Asbestos-related diseases are serious lung disorders that develop as a result of inhaling asbestos particles decades earlier. When asbestos particles are inhaled, they penetrate lung tissue. In response, white blood cells attempt to destroy them by phagocytosis. However, the fibers usually destroy the white blood cells and scarring of lung tissue may follow. Asbestos-related diseases include asbestosis (widespread scarring of lung tissue), diffuse pleural thickening (thickening of the pleurae), and mesothelioma (cancer of the pleurae or, less commonly, the peritoneum).

Sudden Infant Death Syndrome
Sudden infant death syndrome (SIDS) is the sudden, unexpected death of an apparently healthy infant during sleep. It rarely occurs before 2 weeks or after 6 months of age, with the peak incidence between the second and fourth months. SIDS is more common in premature infants, male babies, low-birth-weight babies, babies of drug users or smokers, babies who have stopped breathing and have had to be resuscitated, babies with upper respiratory tract infections, and babies who have had a sibling die of SIDS. African American and Native American babies are at higher risk. The exact cause of SIDS is unknown. However, it may be due to an abnormality in the mechanisms that control respiration or low levels of oxygen in the blood. SIDS may also be linked to hypoxia while sleeping in a prone position (on the stomach) and the rebreathing of exhaled air trapped in a depression of a mattress. It is recommended that for the first six months infants be placed on their backs for sleeping (“back to sleep”).

Severe Acute Respiratory Syndrome
Severe acute respiratory syndrome (SARS) is an example of an emerging infectious disease, that is, a disease that is new or changing. Other examples of emerging infectious diseases are West Nile encephalitis, mad cow disease, and AIDS. SARS first appeared in Southern China in late 2002 and has subsequently spread worldwide. It is a respiratory illness caused by a new variety of coronavirus. Symptoms of SARS include fever, malaise, muscle aches, nonproductive (dry) cough, difficulty in breathing, chills, headache, and diarrhea. About 10–20% of patients require mechanical ventilation and in some cases inserted into the trachea. The disease is primarily spread through person-to-person contact. There is no effective treatment for SARS and the death rate is 5–10%, usually among the elderly and in persons with other medical problems.

MEDICAL TERMINOLOGY
Abdominal thrust maneuver First-aid procedure designed to clear the airways of obstructing objects. It is performed by applying a quick upward thrust between the navel and costal margin that causes sudden elevation of the diaphragm and forceful, rapid expulsion of air in the lungs; this action forces air out the trachea to eject the obstructing object. The abdominal thrust maneuver is also used to expel water from the lungs of near-drowning victims before resuscitation is begun. Previously called the Heimlich maneuver (HĪ-mlik ma-NOO-ver).

Asphyxia (as-FIK-se-a; sphyxia = pulse) Oxygen starvation due to low atmospheric oxygen or interference with ventilation, external respiration, or internal respiration.

Aspiration (as’-pi-RĀ-shun) Inhalation of a foreign substance such as water, food, or a foreign body into the bronchial tree; also, the drawing of a substance in or out by suction.

Avian influenza A respiratory disorder that has resulted in the deaths of hundreds of millions of birds worldwide. It is usually transmitted from one bird to another bird through their droppings, saliva, and nasal secretions. Currently, avian influenza is difficult to transmit from birds to humans; the few humans who have died from avian influenza have had close contact with infected birds. Also called bird flu.

Black lung disease A condition in which the lungs appear black instead of pink due to inhalation of coal dust over a period of many years. Most often it affects people who work in the coal industry.

Bronchiectasis (bron’-kē-EK-ta-sis; ek-tasis = stretching) A chronic dilation of the bronchi or bronchioles resulting from damage to the bronchial wall, for example, from respiratory infections.

Bronchography (bron-KOG-ra-fē) An imaging technique used to visualize the bronchial tree using x-rays. After an opaque contrast medium is inhaled through an intratracheal catheter, radiographs of the chest in various positions are taken, and the developed film, a bronchogram (BRON-kō-gram), provides a picture of the bronchial tree.

Bronchoscopy (bron-KOS-kō-pē) Visual examination of the bronchi through a bronchoscope, an illuminated, flexible tubular instrument that is passed through the mouth (or nose), larynx, and trachea into the bronchi. The examiner can view the interior of the trachea and bronchi to biopsy a tumor, clear an obstructing object or secretions from an airway, take cultures or smears for microscopic examination, stop bleeding, or deliver drugs.

Cheyne–Stokes respiration (CHĀN STOKS res’-pi-RĀ-shun) A repeated cycle of irregular breathing that begins with shallow breaths that increase in depth and rapidity and then decrease and cease altogether for 15 to 20 seconds. Cheyne-Stokes is normal in infants; it is also often seen just before death from pulmonary, cerebral, cardiac, and kidney disease.

Dyspnea (DISP-nē-a; dys- = painful, difficult) Painful or labored breathing.

Epistaxis (ep’-i-STAK-sis) Loss of blood from the nose due to trauma, infection, allergy, malignant growths, or bleeding disorders. It can be arrested by cautery with silver nitrate, electrocautery, or firm packing. Also called nosebleed.

Hypoventilation (hy-pō- = below) Slow and shallow breathing.

Mechanical ventilation The use of an automatically cycling device (ventilator or respirator) to assist breathing. A plastic tube is inserted into the nose or mouth and the tube is attached to a device that forces air into the lungs. Exhalation occurs passively due to the elastic recoil of the lungs.

Rales (RĀLS) Sounds sometimes heard in the lungs that resemble bubbling or rattling. Rales are to the lungs what murmurs are to the heart. Different types are due to the presence of an abnormal type or amount of fluid or mucus within the bronchi or alveoli, or to bronchoconstriction that causes turbulent airflow.

Respirator (RES-pī-rā-’toor) An apparatus fitted to a mask over the nose and mouth, or hooked directly to an endotracheal or tracheotomy tube, that is used to assist or support ventilation or to provide nebulized medication to the air passages.
Respiratory failure A condition in which the respiratory system either cannot supply sufficient O₂ to maintain metabolism or cannot eliminate enough CO₂ to prevent respiratory acidosis (a lower-than-normal pH in interstitial fluid).

Rhinitis (rı̊-NI̊-tis; rhin- = nose) Chronic or acute inflammation of the mucous membrane of the nose due to viruses, bacteria, or irritants. Excessive mucus production produces a runny nose, nasal congestion, and postnasal drip.

Sleep apnea (AP-né-a; a- = without; -pnea = breath) A disorder in which a person repeatedly stops breathing for 10 or more seconds while sleeping. Most often, it occurs because loss of muscle tone in pharyngeal muscles allows the airway to collapse.

Sputum (SPŮ-tum = to spit) Mucus and other fluids from the air passages that is expectorated (expelled by coughing).

Strep throat Inflammation of the pharynx caused by the bacterium Streptococcus pyogenes. It may also involve the tonsils and middle ear.

Tachypnea (tak'-ip-NÉ-a; tachy- = rapid; -pnea = breath) Rapid breathing rate.

Wheeze (HWEEZ) A whistling, squeaking, or musical high-pitched sound during breathing resulting from a partially obstructed airway.

### Study Outline

#### Respiratory System Anatomy (p. 875)

1. The respiratory system consists of the nose, pharynx, larynx, trachea, bronchi, and lungs. They act with the cardiovascular system to supply oxygen (O₂) and remove carbon dioxide (CO₂) from the blood.

2. The external portion of the nose is made of cartilage and skin and is lined with a mucous membrane. Openings to the exterior are the external nares.

3. The internal portion of the nose communicates with the paranasal sinuses and nasopharynx through the internal nares.

4. The nasal cavity is divided by a septum. The anterior portion of the cavity is called the vestibule. The nose warms, moistens, and filters air and functions in olfaction and speech.

5. The pharynx (throat) is a muscular tube lined by a mucous membrane. The anatomic regions are the nasopharynx, oropharynx, and laryngopharynx.

6. The nasopharynx functions in respiration. The oropharynx and laryngopharynx function both in digestion and in respiration.

7. The larynx (voice box) is a passageway that connects the pharynx with the trachea. It contains the thyroid cartilage (Adam’s apple); the epiglottis, which prevents food from entering the larynx; the cricoid cartilage, which connects the larynx and trachea; and the paired arytenoid, corniculate, and cuneiform cartilages.

8. The larynx contains vocal folds, which produce sound as they vibrate. Taut folds produce high pitches, and relaxed ones produce low pitches.

9. The trachea (windpipe) extends from the larynx to the primary bronchi. It is composed of C-shaped rings of cartilage and smooth muscle and is lined with pseudostratified ciliated columnar epithelium.

10. The bronchial tree consists of the trachea, primary bronchi, secondary bronchi, tertiary bronchi, bronchioles, and terminal bronchioles. Walls of bronchi contain rings of cartilage; walls of bronchioles contain increasingly smaller plates of cartilage and increasing amounts of smooth muscle.

11. Lungs are paired organs in the thoracic cavity enclosed by the pleural membrane. The parietal pleura is the superficial layer that lines the thoracic cavity; the visceral pleura is the deep layer that covers the lungs.

12. The right lung has three lobes separated by two fissures; the left lung has two lobes separated by one fissure and a depression, the cardiac notch.

13. Secondary bronchi give rise to branches called segmental bronchi, which supply segments of lung tissue called bronchopulmonary segments.

14. Each bronchopulmonary segment consists of lobules, which contain lymphatics, arterioles, venules, terminal bronchioles, respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli.

15. Alveolar walls consist of type I alveolar cells, type II alveolar cells, and associated alveolar macrophages.

16. Gas exchange occurs across the respiratory membranes.

#### Pulmonary Ventilation (p. 890)

1. Pulmonary ventilation, or breathing, consists of inhalation and exhalation.

2. The movement of air into and out of the lungs depends on pressure changes governed in part by Boyle’s law, which states that the volume of a gas varies inversely with pressure, assuming that temperature remains constant.

3. Inhalation occurs when alveolar pressure falls below atmospheric pressure. Contraction of the diaphragm and external intercostals increases the size of the thorax, thereby decreasing the intrapleural pressure so that the lungs expand. Expansion of the lungs decreases alveolar pressure so that air moves down a pressure gradient from the atmosphere into the lungs.

4. During forceful inhalation, accessory muscles of inhalation (sternocleidomastoids, scalenes, and pectoralis minors) are also used.

5. Exhalation occurs when alveolar pressure is higher than atmospheric pressure. Relaxation of the diaphragm and external intercostals results in elastic recoil of the chest wall and lungs, which increases intrapleural pressure; lung volume decreases and alveolar pressure increases, so air moves from the lungs to the atmosphere.

6. Forceful exhalation involves contraction of the internal intercostal and abdominal muscles.

7. The surface tension exerted by alveolar fluid is decreased by the presence of surfactant.

8. Compliance is the ease with which the lungs and thoracic wall can expand.
9. The walls of the airways offer some resistance to breathing.

10. Normal quiet breathing is termed eupnea; other patterns are costal breathing and diaphragmatic breathing. Modified respiratory movements, such as coughing, sneezing, sighing, yawning, sobbing, crying, laughing, and hiccupping, are used to express emotions and to clear the airways. (See Table 23.1 on page 895.)

**Lung Volumes and Capacities (p. 894)**

1. Lung volumes exchanged during breathing and the rate of respiration are measured with a spirometer.

2. Lung volumes measured by spirometry include tidal volume, minute ventilation, alveolar ventilation rate, inspiratory reserve volume, expiratory reserve volume, and FEV10. Other lung volumes include anatomic dead space, residual volume, and minimal volume.

3. Lung capacities, the sum of two or more lung volumes, include inspiratory, functional, residual, vital, and total lung capacities.

**Exchange of Oxygen and Carbon Dioxide (p. 896)**

1. The partial pressure of a gas is the pressure exerted by that gas in a mixture of gases. It is symbolized by $P_x$, where the subscript is the chemical formula of the gas.

2. According to Dalton's law, each gas in a mixture of gases exerts its own pressure as if all the other gases were not present.

3. Henry’s law states that the quantity of a gas that will dissolve in a liquid is proportional to the partial pressure of the gas and its solubility (given that the temperature remains constant).

4. In internal and external respiration, $O_2$ and $CO_2$ diffuse from areas of higher partial pressures to areas of lower partial pressures.

5. External respiration or pulmonary gas exchange is the exchange of gases between alveoli and pulmonary blood capillaries. It depends on partial pressure differences, a large surface area for gas exchange, a small diffusion distance across the respiratory membrane, and the rate of airflow into and out of the lungs.

6. Internal respiration or systemic gas exchange is the exchange of gases between systemic blood capillaries and tissue cells.

**Transport of Oxygen and Carbon Dioxide (p. 900)**

1. In each 100 mL of oxygenated blood, 1.5% of the $O_2$ is dissolved in blood plasma and 98.5% is bound to hemoglobin as oxyhemoglobin ($Hb-O_2$).

2. The binding of $O_2$ to hemoglobin is affected by $P_{O_2}$, acidity (pH), $P_{CO_2}$, temperature, and 2,3-bisphosphoglycerate (BPG).

3. Fetal hemoglobin differs from adult hemoglobin in structure and has a higher affinity for $O_2$.

4. In each 100 mL of deoxygenated blood, 7% of $CO_2$ is dissolved in blood plasma, 23% combines with hemoglobin as carbaminohemoglobin ($Hb-CO_2$), and 70% is converted to bicarbonate ions ($HCO_3^-$).

5. In an acidic environment, hemoglobin’s affinity for $O_2$ is lower, and $O_2$ dissociates more readily from it (Bohr effect).

6. In the presence of $O_2$, less $CO_2$ binds to hemoglobin (Haldane effect).

**Control of Respiration (p. 905)**

1. The respiratory center consists of a medullary rhythmicity area in the medulla oblongata and a pneumotaxic area and an apneustic area in the pons.

2. The inspiratory area sets the basic rhythm of respiration.

3. The pneumotaxic and apneustic areas coordinate the transition between inhalation and exhalation.

4. Respirations may be modified by a number of factors, including cortical influences; the inflation reflex; chemical stimuli, such as $O_2$ and $CO_2$ and $H^+$ levels; proprioceptor input; blood pressure changes; limbic system stimulation; temperature; pain; and irritation to the airways. (See Table 23.2 on page 909.)

**Exercise and the Respiratory System (p. 910)**

1. The rate and depth of ventilation change in response to both the intensity and duration of exercise.

2. An increase in pulmonary perfusion and $O_2$-diffusing capacity occurs during exercise.

3. The abrupt increase in ventilation at the start of exercise is due to neural changes that send excitatory impulses to the inspiratory area in the medulla oblongata. The more gradual increase in ventilation during moderate exercise is due to chemical and physical changes in the bloodstream.

**Development of the Respiratory System (p. 910)**

1. The respiratory system begins as an outgrowth of endoderm called the respiratory diverticulum.

2. Smooth muscle, cartilage, and connective tissue of the bronchial tubes and pleural sacs develop from mesoderm.

**Aging and the Respiratory System (p. 911)**

1. Aging results in decreased vital capacity, decreased blood level of $O_2$, and diminished alveolar macrophage activity.

2. Elderly people are more susceptible to pneumonia, emphysema, bronchitis, and other pulmonary disorders.
1. Oxygen in blood is carried primarily in the form of _____; carbon dioxide is carried as _____, _____, and _____.

2. Write the equation for the chemical reaction that occurs for the transport of carbon dioxide as bicarbonate ions in blood: _____.

Choose the one best answer to the following questions.

5. What structural changes occur from primary bronchi to terminal bronchioles? (a) The mucous membrane changes from pseudostratified ciliated columnar epithelium to nonciliated simple cuboidal epithelium. (b) The number of goblet cells increases. (c) The amount of smooth muscle increases. (d) Incomplete rings of cartilage disappear. (e) The amount of branching decreases.

(a) 1, 2, 3, 4, and 5 (b) 2, 3, and 4 (c) 1, 3, and 4
(d) 1, 3, 4, and 5 (e) 1, 2, 3, and 4

6. Which of the following would cause oxygen to dissociate more readily from hemoglobin? (a) low P_{O_2}, (b) an increase in H^+ in blood, (c) hypercapnia, (d) hypothermia, (e) low levels of BPG (2,3-bisphosphoglycerate).

(a) 1 and 2 (b) 2, 3, and 4 (c) 1, 2, 3, and 5
(d) 1, 3, and 5 (e) 1, 2, 3, and 4

7. Which of the following statements are correct? (1) Normal exhalation during quiet breathing is an active process involving intensive muscle contraction. (2) Passive exhalation results from elastic recoil of the chest wall and lungs. (3) Air flow during breathing is due to a pressure gradient between the lungs and the atmospheric air. (4) During normal breathing, the pressure between the two pleural layers (intrapleural pressure) is always subatmospheric. (5) Surface tension of alveolar fluid facilitates inhalation. (6) Increased aeration during quiet breathing is an active process involving intensive muscle contraction.

(a) 1, 2, and 3 (b) 2, 3, and 4 (c) 3, 4, and 5
(d) 1, 3, and 5 (e) 2, 3, and 5

8. Which of the following factors affect the rate of external respiration? (1) partial pressure differences of the gases, (2) surface area for gas exchange, (3) diffusion distance, (4) solubility and molecular weight of the gases, (5) presence of bisphosphoglycerate (BPG).

(a) 1, 2, and 3 (b) 2, 4, and 5 (c) 1, 2, 4, and 5
(d) 1, 2, 3, and 4 (e) 2, 3, 4, and 5

9. The most important factor in determining the percent oxygen saturation of hemoglobin is (a) the partial pressure of oxygen, (b) acidity, (c) the partial pressure of carbon dioxide, (d) temperature, (e) BPG.

10. Which of the following statements are true? (1) Peripheral and central chemoreceptors are stimulated by an increase in P_{CO_2} and H^+ and a decrease in O_2. (2) Respiratory rate increases during the initial onset of exercise due to input to the inspiratory area from proprioceptors. (3) When baroreceptors in the lungs are stimulated, the expiratory area is activated. (4) Stimulation of the limbic system can result in excitation of the inspiratory area. (5) Sudden severe pain causes brief apnea, while prolonged somatic pain causes an increase in respiratory rate.

(a) 1, 2, and 6 (b) 1, 2, 4, and 5 (c) 1, 2, 4, 5, and 6
(d) 2, 3, 4, 5, and 6 (e) 2, 4, 5, and 6

11. Indicate whether the following statements are true or false.

(a) Decrease in intrapleural pressure to 754mmHg (b) Inhale in the size of the thoracic cavity (c) Flow of air from higher to lower pressure (d) Outward pull of pleurae, resulting in lung expansion (e) Stimulation of primary breathing muscles by phrenic and intercostal nerves

(f) Decrease in alveolar pressure to 758mmHg (g) Contraction of the diaphragm and external intercostals (h) Increase in the volume of the pleural cavity

12. Place the steps for normal inhalation in order.

(a) decrease in intrapleural pressure to 754mmHg (b) increase in the size of the thoracic cavity (c) flow of air from higher to lower pressure (d) outward pull of pleurae, resulting in lung expansion (e) stimulation of primary breathing muscles by phrenic and intercostal nerves

(f) decrease in alveolar pressure to 758mmHg (g) contraction of the diaphragm and external intercostals (h) increase in the volume of the pleural cavity

13. Place the steps for normal exhalation in order.

(a) decrease in intrapleural pressure to 754mmHg (b) increase in the size of the thoracic cavity (c) flow of air from lower to higher pressure (d) inward pull of pleurae, resulting in lung deflation (e) stimulation of the expiratory area

(f) decrease in alveolar pressure to 758mmHg (g) contraction of the diaphragm and external intercostals (h) increase in the volume of the pleural cavity

14. Choose the one best answer to the following questions.

1. Indicate the type of epithelium lining the end of the alveoli. (a) simple squamous (b) simple cuboidal (c) pseudostratified ciliated columnar (d) stratified squamous (e) stratified columnar

2. Which part of the respiratory system is responsible for gas exchange? (a) the nasal cavity (b) the pharynx (c) the larynx (d) the trachea (e) the alveoli

3. Identify the term that refers to the distance between the gas exchange site and the blood. (a) diffusion distance (b) perfusion distance (c) ventilation distance (d) blood-gas barrier distance (e) gas exchange distance

4. Which component of the respiratory system is responsible for mixing the inspired gas with the previously expired gas? (a) the nasal cavity (b) the pharynx (c) the larynx (d) the trachea (e) the bronchi

5. Match the following structures to their descriptions.

(a) nasal cavity (b) pharynx (c) larynx (d) trachea (e) bronchi

(f) receives olfactory stimuli; moistering, and filtering air; receives olfactory stimuli; (g) resonating chamber for sound; (h) a tubular passageway for air connecting the larynx to the bronchi (i) secrete alveolar fluid and lining of the alveolar wall; sites of gas exchange (j) functions as a passageway for air and food, provides a resonating chamber for speech sounds, and houses the tonsils (k) connects the laryngopharynx with the trachea; houses the vocal cords (l) air passageways entering the larynx; landmark for tracheotomy (m) ridge covered by a sensitive mucous membrane; irritation triggers cough reflex (n) type I alveolar cells (o) type II alveolar cells (p) type II alveolar cells

(f) receives olfactory stimuli; (g) resonating chamber for sound; (h) a tubular passageway for air connecting the larynx to the bronchi (i) secrete alveolar fluid and lining of the alveolar wall; sites of gas exchange (j) functions as a passageway for air and food, provides a resonating chamber for speech sounds, and houses the tonsils (k) connects the laryngopharynx with the trachea; houses the vocal cords (l) air passageways entering the larynx; landmark for tracheotomy (m) ridge covered by a sensitive mucous membrane; irritation triggers cough reflex (n) type I alveolar cells (o) type II alveolar cells (p) type II alveolar cells
13. Match the following:
   (a) a deficiency of oxygen at the tissue level
   (b) above-normal partial pressure of carbon dioxide
   (c) normal quiet breathing
   (d) deep, abdominal breathing
   (e) the ease with which the lungs and thoracic wall can be expanded
   (f) hypoxia-induced vasoconstriction to divert pulmonary blood from poorly ventilated to well-ventilated regions of the lungs
   (g) absence of breathing
   (h) rapid and deep breathing
   (i) shallow, chest breathing

14. Match the following:
   (a) total volume of air inhaled and exhaled each minute
   (b) tidal volume + inspiratory reserve volume + expiratory reserve volume
   (c) additional amount of air inhaled beyond tidal volume when taking a very deep breath
   (d) residual volume + expiratory reserve volume
   (e) amount of air remaining in lungs after expiratory reserve volume is expelled
   (f) tidal volume + inspiratory reserve volume
   (g) vital capacity + residual volume
   (h) volume of air in one breath
   (i) amount of air exhaled in forced exhalation
   (j) provides a medical and legal tool for determining if a baby was born dead or died after birth

15. Match the following:
   (a) prevents excessive inflation of the lungs
   (b) the lower the amount of oxyhemoglobin, the higher the carbon dioxide carrying capacity of the blood
   (c) controls the basic rhythm of respiration
   (d) active during normal inhalation; sends nerve impulses to external intercostals and diaphragm
   (e) sends stimulatory impulses to the inspiratory area that activate it and prolong inhalation
   (f) as acidity increases, the affinity of hemoglobin for oxygen decreases and oxygen dissociates more readily from hemoglobin; shifts oxygen-dissociation curve to the right
   (g) active during forceful exhalation
   (h) pressure of a gas in a closed container is inversely proportional to the volume of the container
   (i) transmits inhibitory impulses to turn off the inspiratory area before the lungs become too full of air
   (j) the quantity of a gas that dissolves in a liquid is proportional to the partial pressure of the gas and its solubility
   (k) relates to the partial pressure of a gas in a mixture of gases whereby each gas in a mixture exerts its own pressure as if all the other gases were not present

1. (1) eupnea
   (2) apnea
   (3) hyperventilation
   (4) costal breathing
   (5) diaphragmatic breathing
   (6) compliance
   (7) hypoxia
   (8) hypercapnia
   (9) ventilation–perfusion coupling

2. (1) tidal volume
   (2) residual volume
   (3) minute ventilation
   (4) expiratory reserve volume
   (5) inspiratory reserve volume
   (6) minimal volume
   (7) inspiratory capacity
   (8) vital capacity
   (9) functional residual volume
   (10) total lung capacity

3. (1) Bohr effect
   (2) Dalton’s law
   (3) medullary rhythmicty area
   (4) inspiratory area
   (5) expiratory area
   (6) apneustic area
   (7) pneumotaxic area
   (8) Henry’s law
   (9) inflation (Hering–Breuer) reflex
   (10) Boyle’s law
   (11) Haldane effect
CHAPTER 23 • THE RESPIRATORY SYSTEM

23.1 The conducting zone of the respiratory system includes the nose, pharynx, larynx, trachea, bronchi, and bronchioles (except the respiratory bronchioles).

23.2 The path of air is external nares → vestibule → nasal cavity → internal nares.

23.3 The root of the nose attaches it to the frontal bone.

23.4 During swallowing, the epiglottis closes over the rima glottidis, the entrance to the trachea, to prevent aspiration of food and liquids into the lungs.

23.5 The main function of the vocal folds is voice production.

23.6 Because the tissues between the esophagus and trachea are soft, the esophagus can bulge and press against the trachea during swallowing.

23.7 The left lung has two lobes and two secondary bronchi; the right lung has three of each.

23.8 The pleural membrane is a serous membrane.

23.9 Because two-thirds of the heart lies to the left of the midline, the left lung contains a cardiac notch to accommodate the presence of the heart. The right lung is shorter than the left because the diaphragm is higher on the right side to accommodate the liver.

23.10 The wall of an alveolus is made up of type I alveolar cells, type II alveolar cells, and associated alveolar macrophages.

23.11 The respiratory membrane averages 0.5 μm in thickness.

23.12 The pressure would increase fourfold, to 4 atm.

23.13 If you are at rest while reading, your diaphragm is responsible for about 75% of each inhalation.

23.14 At the start of inhalation, intrapleural pressure is about 756 mmHg. With contraction of the diaphragm, it decreases to about 754 mmHg as the volume of the space between the two pleural layers expands. With relaxation of the diaphragm, it increases back to 756 mmHg.

23.15 Normal atmospheric pressure at sea level is 760 mmHg.

23.16 Breathing in and then exhaling as much air as possible demonstrates vital capacity.

23.17 A difference in P_O2 promotes oxygen diffusion into pulmonary capillaries from alveoli and into tissue cells from systemic capillaries.

23.18 The most important factor that determines how much O_2 binds to hemoglobin is the P_O2.

23.19 Both during exercise and at rest, hemoglobin in your pulmonary veins would be fully saturated with O_2, a point that is at the upper right of the curve.

23.20 Because lactic acid (lactate) and CO_2 are produced by active skeletal muscles, blood pH decreases slightly and P_CO2 increases when you are actively exercising. The result is lowered affinity of hemoglobin for O_2, so more O_2 is available to the working muscles.

23.21 O_2 is more available to your tissue cells when you have a fever because the affinity of hemoglobin for O_2 decreases with increasing temperature.

23.22 At a P_O2 of 40 mmHg, fetal Hb is 80% saturated with O_2 and maternal Hb is about 75% saturated.

23.23 Blood in a systemic vein would have a higher concentration of HCO_3^-.

23.24 The medullary inspiratory area contains autorhythmic neurons that are active and then inactive in a repeating cycle.

23.25 The phrenic nerves innervate the diaphragm.

23.26 Peripheral chemoreceptors are responsive to changes in blood levels of oxygen, carbon dioxide, and H^+.

23.27 Normal arterial P_CO2 is 40 mmHg.

23.28 The respiratory system begins to develop about 4 weeks after fertilization.
THE DIGESTIVE SYSTEM

THE DIGESTIVE SYSTEM AND HOMEOSTASIS

The digestive system contributes to homeostasis by breaking down food into forms that can be absorbed and used by body cells. It also absorbs water, vitamins, and minerals, and eliminates wastes from the body.

The food we eat contains a variety of nutrients, which are used for building new body tissues and repairing damaged tissues. Food is also vital to life because it is our only source of chemical energy. However, most of the food we eat consists of molecules that are too large to be used by body cells. Therefore, foods must be broken down into molecules that are small enough to enter body cells, a process known as digestion (dis = apart; gerere = to carry). The organs involved in the breakdown of food—collectively called the digestive system—are the focus of this chapter. Like the respiratory system, the digestive system is a tubular system. It extends from the mouth to the anus, forms an extensive surface area in contact with the external environment, and is closely associated with the cardiovascular system. The combination of extensive environmental exposure and close association with blood vessels is essential for processing the food that we eat.

The medical specialty that deals with the structure, function, diagnosis, and treatment of diseases of the stomach and intestines is called gastroenterology (gas’-trō-en’-ter-OL-ŏ-jē; gastro- = stomach; entero- = intestines; -logy = study of). The medical specialty that deals with the diagnosis and treatment of disorders of the rectum and anus is called proctology (prok-TOL-ŏ-jē; proct- = rectum).
Two groups of organs compose the digestive system (Figure 24.1): the gastrointestinal (GI) tract and the accessory digestive organs. The gastrointestinal (GI) tract, or alimentary canal (alimentary = nourishment), is a continuous tube that extends from the mouth to the anus through the thoracic and abdominopelvic cavities. Organs of the gastrointestinal tract include the mouth, most of the pharynx, esophagus, stomach, small intestine, and large intestine. The length of the GI tract is about 5–7 meters (16.5–23 ft) in a living person. It is longer in a cadaver (about 7–9 meters or 23–29.5 ft) because the muscles along the wall of the GI tract organs are in a state of tonus (sustained contraction). The accessory digestive organs include the teeth, tongue, salivary glands, liver, gallbladder, and pancreas. Teeth aid in the physical breakdown of food, and the tongue assists in chewing and swallowing. The other accessory digestive organs, however, never come into direct contact with food. They produce or store secretions that flow into the GI tract through ducts; the secretions aid in the chemical breakdown of food.

The GI tract contains food from the time it is eaten until it is digested and absorbed or eliminated. Muscular contractions in the wall of the GI tract physically break down the food by churning it and propel the food along the tract, from the esophagus to the anus. The contractions also help to dissolve foods by mixing them with fluids secreted into the tract. Enzymes secreted by accessory digestive organs and cells that line the tract break down the food chemically.

Figure 24.1 Organs of the digestive system.

Organs of the gastrointestinal (GI) tract are the mouth, pharynx, esophagus, stomach, small intestine, and large intestine. Accessory digestive organs include the teeth, tongue, salivary glands, liver, gallbladder, and pancreas.
Overall, the digestive system performs six basic processes:

1. **Ingestion.** This process involves taking foods and liquids into the mouth (eating).
2. **Secretion.** Each day, cells within the walls of the GI tract and accessory digestive organs secrete a total of about 7 liters of water, acid, buffers, and enzymes into the lumen (interior space) of the tract.
3. **Mixing and propulsion.** Alternating contractions and relaxations of smooth muscle in the walls of the GI tract mix food and secretions and propel them toward the anus. This capability of the GI tract to mix and move material along its length is called **motility.**
4. **Digestion.** Mechanical and chemical processes break down ingested food into small molecules. In **mechanical digestion** the teeth cut and grind food before it is swallowed, and then smooth muscles of the stomach and small intestine churn the food. As a result, food molecules become dissolved and thoroughly mixed with digestive enzymes. In **chemical digestion** the large carbohydrate, lipid, protein, and nucleic acid molecules in food are split into smaller molecules by hydrolysis (see Figure 2.15 on page 45). Digestive enzymes produced by the salivary glands, tongue, stomach, pancreas, and small intestine catalyze these catabolic reactions. A few substances in food can be absorbed without chemical digestion. These include vitamins, ions, cholesterol, and water.
5. **Absorption.** The entrance of ingested and secreted fluids, ions, and the products of digestion into the epithelial cells lining the lumen of the GI tract is called **absorption.** The absorbed substances pass into blood or lymph and circulate to cells throughout the body.
6. **Defecation.** Wastes, indigestible substances, bacteria, cells sloughed from the lining of the GI tract, and digested materials that were not absorbed in their journey through the digestive tract leave the body through the anus in a process called **defecation.** The eliminated material is termed **feces.**

**CHECKPOINT**

1. Which components of the digestive system are GI tract organs, and which are accessory digestive organs?
2. Which organs of the digestive system come in contact with food, and what are some of their digestive functions?
3. Which kinds of food molecules undergo chemical digestion, and which do not?

---

Which structures of the digestive system secrete digestive enzymes?
LAYERS OF THE GI TRACT

**OBJECTIVE**
- Describe the structure and function of the layers that form the wall of the gastrointestinal tract.

The wall of the GI tract from the lower esophagus to the anal canal has the same basic, four-layered arrangement of tissues. The four layers of the tract, from deep to superficial, are the mucosa, submucosa, muscularis, and serosa (Figure 24.2).

**Mucosa**

The *mucosa*, or inner lining of the GI tract, is a mucous membrane. It is composed of (1) a layer of epithelium in direct contact with the contents of the GI tract, (2) a layer of connective tissue called the lamina propria, and (3) a thin layer of smooth muscle (muscularis mucosae).

1. The *epithelium* in the mouth, pharynx, esophagus, and anal canal is mainly nonkeratinized stratified squamous epithelium that serves a protective function. Simple columnar epithelium, which functions in secretion and absorption, lines the stomach and intestines. The tight junctions that firmly seal neighboring simple columnar epithelial cells to one another restrict leakage between the cells. The rate of renewal of GI tract epithelial cells is rapid: Every 5 to 7 days they slough off and are replaced by new cells. Located among the epithelial cells are exocrine cells that secrete mucus and fluid into the lumen of the tract, and several types of endocrine cells, collectively called *enteroendocrine cells*, that secrete hormones.

2. The *lamina propria* (*lamina* = thin, flat plate; *propria* = one’s own) is areolar connective tissue containing many blood and lymphatic vessels, which are the routes by which nutrients absorbed into the GI tract reach the other tissues of the body. This layer supports the epithelium and binds it to the muscularis mucosae (discussed next). The lamina propria also contains the majority of the cells of the *mucosa-associated lymphatic tissue* (MALT). These prominent lymphatic nodules contain immune system cells that protect against disease (see Chapter 22). MALT is present all along the GI tract, especially in the tonsils, small intestine, appendix, and large intestine.

3. A thin layer of smooth muscle fibers called the *muscularis mucosae* throws the mucous membrane of the stomach and small intestine into many small folds, which increase the surface area for digestion and absorption. Movements of the muscularis mucosae ensure that all absorptive cells are fully exposed to the contents of the GI tract.

*Figure 24.2 Layers of the gastrointestinal tract.* Variations in this basic plan may be seen in the esophagus (Figure 24.9), stomach (Figure 24.12), small intestine (Figure 24.18), and large intestine (Figure 24.23).

The four layers of the GI tract, from deep to superficial, are the mucosa, submucosa, muscularis, and serosa.

What are the functions of the lamina propria?
Submucosa

The submucosa consists of areolar connective tissue that binds the mucosa to the muscularis. It contains many blood and lymphatic vessels that receive absorbed food molecules. Also located in the submucosa is an extensive network of neurons known as the submucosal plexus (to be described shortly). The submucosa may also contain glands and lymphatic tissue.

Muscularis

The muscularis of the mouth, pharynx, and superior and middle parts of the esophagus contains skeletal muscle that produces voluntary swallowing. Skeletal muscle also forms the external anal sphincter, which permits voluntary control of defecation. Throughout the rest of the tract, the muscularis consists of smooth muscle that is generally found in two sheets: an inner sheet of circular fibers and an outer sheet of longitudinal fibers. Involuntary contractions of the smooth muscle help break down food, mix it with digestive secretions, and propel it along the tract. Between the layers of the muscularis is a second plexus of neurons—the myenteric plexus (to be described shortly).

Serosa

Those portions of the GI tract that are suspended in the abdominopelvic cavity have a superficial layer called the serosa. As its name implies, the serosa is a serous membrane composed of areolar connective tissue and simple squamous epithelium (mesothelium). The serosa is also called the visceral peritoneum because it forms a portion of the peritoneum, which we examine in detail shortly. The esophagus lacks a serosa; instead only a single layer of areolar connective tissue called the adventitia forms the superficial layer of this organ.

CHECKPOINT

4. Where along the GI tract is the muscularis composed of skeletal muscle? Is control of this skeletal muscle voluntary or involuntary?

5. Name the four layers of the gastrointestinal tract, and describe their functions.

NEURAL INNERVATION OF THE GI TRACT

OBJECTIVE

• Describe the nerve supply of the GI tract.

The gastrointestinal tract is regulated by an intrinsic set of nerves known as the enteric nervous system and by an extrinsic set of nerves that are part of the autonomic nervous system.

Enteric Nervous System

We first introduced you to the enteric nervous system (ENS), the “brain of the gut,” in Chapter 12. It consists of about 100 million neurons that extend from the esophagus to the anus. The neurons of the ENS are arranged into two plexuses: the myenteric plexus and submucosal plexus (see Figure 24.2). The myenteric plexus (myo- = muscle), or plexus of Auerbach, is located between the longitudinal and circular smooth muscle layers of the muscularis. The submucosal plexus, or plexus of Meissner, is found within the submucosa. The plexuses of the ENS consist of motor neurons, interneurons, and sensory neurons (Figure 24.3). Because the motor neurons of the myenteric plexus supply the longitudinal and circular smooth muscle layers of the muscularis, this plexus mostly controls GI tract motility (movement), particularly the frequency and strength of contraction of the muscularis. The motor neurons of the submucosal plexus supply the secretory cells of the mucosal epithelium, controlling the secretions of the organs of the GI tract. The interneurons of the ENS interconnect the neurons of the myenteric and submucosal plexuses. The sensory neurons of the ENS supply the mucosal epithelium. Some of these sensory neurons function as chemoreceptors, receptors that are activated by the presence of certain chemicals in food located in the lumen of a GI organ. Other sensory neurons function as stretch receptors, receptors that are activated when food distends (stretches) the wall of a GI organ.

Autonomic Nervous System

Although the neurons of the ENS can function independently, they are subject to regulation by the neurons of the autonomic nervous system. The vagus (X) nerves supply parasympathetic fibers to most parts of the GI tract, with the exception of the...
last half of the large intestine, which is supplied with parasympathetic fibers from the sacral spinal cord. The parasympathetic nerves that supply the GI tract form neural connections with the ENS. Parasympathetic preganglionic neurons of the vagus or pelvic splanchnic nerves synapse with parasympathetic postganglionic neurons located in the myenteric and submucosal plexuses. Some of the parasympathetic postganglionic neurons in turn synapse with neurons in the ENS; others directly innervate smooth muscle and glands within the wall of the GI tract. In general, stimulation of the parasympathetic nerves that innervate the GI tract causes an increase in GI secretion and motility by increasing the activity of ENS neurons.

Sympathetic nerves that supply the GI tract arise from the thoracic and upper lumbar regions of the spinal cord. Like the parasympathetic nerves, these sympathetic nerves form neural connections with the ENS. Sympathetic postganglionic neurons synapse with neurons located in the myenteric plexus and the submucosal plexus. In general, the sympathetic nerves that supply the GI tract cause a decrease in GI secretion and motility by inhibiting the neurons of the ENS. Emotions such as anger, fear, and anxiety may slow digestion because they stimulate the sympathetic nerves that supply the GI tract.

**Gastrointestinal Reflex Pathways**

Many neurons of the ENS are components of GI (gastrointestinal) reflex pathways that regulate GI secretion and motility in response to stimuli present in the lumen of the GI tract. The initial components of a typical GI reflex pathway are sensory receptors (such as chemoreceptors and stretch receptors) that are associated with the sensory neurons of the ENS. The axons of these sensory neurons can synapse with other neurons located in the ENS, CNS, or ANS, informing these regions about the nature of the contents and the degree of distension (stretching) of the GI tract. The neurons of the ENS, CNS, or ANS subsequently activate or inhibit GI glands and smooth muscle, altering GI secretion and motility.

**CHECKPOINT**

6. How is the enteric nervous system regulated by the autonomic nervous system?
7. What is a gastrointestinal reflex pathway?

**Figure 24.4** Relationship of the peritoneal folds to one another and to organs of the digestive system.

The size of the peritoneal cavity in (a) is exaggerated for emphasis.

The peritoneum is the largest serous membrane in the body.
**PERITONEUM**

**OBJECTIVE**
- Describe the peritoneum and its folds.

The peritoneum (per'-i-tō-NĒ-um; peri- = around) is the largest serous membrane of the body; it consists of a layer of simple squamous epithelium (mesothelium) with an underlying supporting layer of areolar connective tissue. The peritoneum is divided into the parietal peritoneum, which lines the wall of the abdominopelvic cavity, and the visceral peritoneum, which covers some of the organs in the cavity and is their serosa (Figure 24.4a on page 926). The slim space containing lubricating serous fluid that is between the parietal and visceral portions of the peritoneum is called the peritoneal cavity. In certain diseases, the peritoneal cavity may become distended by the accumulation of several liters of fluid, a condition called ascites (a-SI-tēz).

As you will see shortly, some organs lie on the posterior abdominal wall and are covered by peritoneum only on their anterior surfaces; they are not in the peritoneal cavity. Such organs, including the kidneys, ascending and descending colons of the large intestine, duodenum of the small intestine, and pancreas, are said to be retroperitoneal (retro- = behind).

Unlike the pericardium and pleurae, which smoothly cover the heart and lungs, the peritoneum contains large folds that weave between the viscera. The folds bind the organs to one another and to the walls of the abdominal cavity. They also contain blood vessels, lymphatic vessels, and nerves that supply the abdominal organs. There are five major peritoneal folds: the greater omentum, falciform ligament, lesser omentum, mesentery, and mesocolon.

Which peritoneal fold binds the small intestine to the posterior abdominal wall?
1. The greater omentum (ō-MEN-tum = fat skin), the largest peritoneal fold, drapes over the transverse colon and coils of the small intestine like a “fatty apron” (Figure 24.4a, d). The greater omentum is a double sheet that folds back on itself, giving it a total of four layers. From attachments along the stomach and duodenum, the greater omentum extends downward anterior to the small intestine, then turns and extends upward and attaches to the transverse colon. The greater omentum normally contains a considerable amount of adipose tissue. Its adipose tissue content can greatly expand with weight gain, giving rise to the characteristic “beer belly” seen in some overweight individuals. The many lymph nodes of the greater omentum contribute macrophages and antibody-producing plasma cells that help combat and contain infections of the GI tract.

2. The falciform ligament (FAL-si-form; falc- = sickle-shaped) attaches the liver to the anterior abdominal wall and diaphragm (Figure 24.4b). The liver is the only digestive organ that is attached to the anterior abdominal wall.

3. The lesser omentum arises as an anterior fold in the serosa of the stomach and duodenum, and it suspends the stomach and duodenum from the liver (Figure 24.4a, c). It is the pathway for blood vessels entering the liver and contains the hepatic portal vein, common hepatic artery, and common bile duct, along with some lymph nodes.

4. A fan-shaped fold of the peritoneum, called the mesentery (MEZ-en-ter-eë; mes- = middle), binds the jejunum and ileum of the small intestine to the posterior abdominal wall (Figure 24.4a, d). It extends from the posterior abdominal wall to wrap around the small intestine and then returns to its origin, forming a double-layered structure. Between the two layers are blood and lymphatic vessels and lymph nodes.

5. Two separate folds of peritoneum, called the mesocolon (mez'-ō-KÖ-lon), bind the transverse colon (transverse mesocolon) and sigmoid colon (sigmoid mesocolon) of the large intestine to the posterior abdominal wall (Figure 24.4a). It also carries blood and lymphatic vessels to the intestines. Together, the mesentery and mesocolon hold the intestines loosely in place, allowing movement as muscular contractions mix and move the luminal contents along the GI tract.

### MOUTH

#### OBJECTIVES
- Identify the locations of the salivary glands, and describe the functions of their secretions.
- Describe the structure and functions of the tongue.
- Identify the parts of a typical tooth, and compare deciduous and permanent dentitions.

The mouth, also referred to as the oral or buccal cavity (BUK-al; bucca = cheeks), is formed by the cheeks, hard and soft palates, and tongue (Figure 24.5). The cheeks form the lateral walls of the oral cavity. They are covered externally by skin and internally by a mucous membrane, which consists of nonkeratinized stratified squamous epithelium. Buccinator muscles and connective tissue lie between the skin and mucous membranes of the cheeks. The anterior portions of the cheeks end at the lips.

The lips or labia (= fleshy borders) are fleshy folds surrounding the opening of the mouth. They contain the orbicularis oris muscle and are covered externally by skin and internally by a mucous membrane. The inner surface of each lip is attached to its corresponding gum by a midline fold of mucous membrane called the labial frenulum (LĀ-bē-al FREN-ū-lum; frenulum = small bridle). During chewing, contraction of the buccinator muscles in the cheeks and orbicularis oris muscle in the lips helps keep food between the upper and lower teeth. These muscles also assist in speech.

The oral vestibule (= entrance to a canal) of the oral cavity is a space bounded externally by the cheeks and lips and internally by the gums and teeth. The oral cavity proper is a space that extends from the gums and teeth to the faucæ (FAW-sēs = passages), the opening between the oral cavity and the oropharynx (throat).

The palate is a wall or septum that separates the oral cavity from the nasal cavity, forming the roof of the mouth. This important structure makes it possible to chew and breathe at the same time. The hard palate—the anterior portion of the roof of the mouth—is formed by the maxillae and palatine bones and is covered by a mucous membrane; it forms a bony partition between the oral and nasal cavities. The soft palate, which forms the posterior portion of the roof of the mouth, is an arch-shaped muscular partition between the oropharynx and nasopharynx that is lined with mucous membrane.

Hanging from the free border of the soft palate is a conical muscular process called the uvula (Ū-vū-la = little grape). During swallowing, the soft palate and uvula are drawn superiorly, closing off the nasopharynx and preventing swallowed...
foods and liquids from entering the nasal cavity. Lateral to the base of the uvula are two muscular folds that run down the lateral sides of the soft palate: Anteriorly, the **palatoglossal arch** extends to the side of the base of the tongue; posteriorly, the **palatopharyngeal arch** (PAL-a-tō-fa-rin′-jē-al) extends to the side of the pharynx. The palatine tonsils are situated between the arches, and the lingual tonsils are situated at the base of the tongue. At the posterior border of the soft palate, the mouth opens into the oropharynx through the fauces (Figure 24.5).

**Salivary Glands**

A **salivary gland** is a gland that releases a secretion called saliva into the oral cavity. Ordinarily, just enough saliva is secreted to keep the mucous membranes of the mouth and pharynx moist and to cleanse the mouth and teeth. When food enters the mouth, however, secretion of saliva increases, and it lubricates, dissolves, and begins the chemical breakdown of the food.

The mucous membrane of the mouth and tongue contains many small salivary glands that open directly, or indirectly via short ducts, to the oral cavity. These glands include **labial, buccal, and palatal glands** in the lips, cheeks, and palate, respectively, and **lingual glands** in the tongue, all of which make a small contribution to saliva.

However, most saliva is secreted by the **major salivary glands**, which lie beyond the oral mucosa, into ducts that lead to the oral cavity. There are three pairs of major salivary glands: the parotid, submandibular, and sublingual glands (Figure 24.6a). The **parotid glands** (par- = near; to- = ear) are located inferior and anterior to the ears, between the skin and the masseter muscle. Each secretes saliva into the oral cavity via a **parotid duct** that pierces the buccinator muscle to open into the vestibule opposite the second maxillary (upper) molar tooth. The **submandibular glands** are found in the floor of the mouth; they are medial and partly inferior to the body of the mandible. Their ducts, the **submandibular ducts**, run under the mucosa on either side of the midline of the floor of the mouth and enter the oral cavity proper lateral to the lingual frenulum. The **sublingual glands** are beneath the tongue and superior to the submandibular glands. Their ducts, the **lesser sublingual ducts**, open into the floor of the mouth in the oral cavity proper.

**Figure 24.5** Structures of the mouth (oral cavity).

*The mouth is formed by the cheeks, hard and soft palates, and tongue.*
Composition and Functions of Saliva

Chemically, saliva is 99.5% water and 0.5% solutes. Among the solutes are ions, including sodium, potassium, chloride, bicarbonate, and phosphate. Also present are some dissolved gases and various organic substances, including urea and uric acid, mucus, immunoglobulin A, the bacteriolytic enzyme lysozyme, and salivary amylase, a digestive enzyme that acts on starch.

Not all salivary glands supply the same ingredients. The parotid glands secrete a watery (serous) liquid containing salivary amylase. Because the submandibular glands contain cells similar to those found in the parotid glands, plus some mucous cells, they secrete a fluid that contains amylase but is thickened with mucus. The sublingual glands contain mostly mucous cells, so they secrete a much thicker fluid that contributes only a small amount of salivary amylase.

The water in saliva provides a medium for dissolving foods so that they can be tasted by gustatory receptors and so that digestive reactions can begin. Chloride ions in the saliva activate salivary amylase, an enzyme that starts the breakdown of starch. Bicarbonate and phosphate ions buffer acidic foods that enter the mouth, so saliva is only slightly acidic (pH 6.35–6.85). Salivary glands (like the sweat glands of the skin) help remove waste molecules from the body, which accounts for the presence of urea and uric acid in saliva. Mucus lubricates food so it can be moved around easily in the mouth, formed into a ball, and swallowed. Immunoglobulin A (IgA) prevents attachment of microbes so they cannot penetrate the epithelium, and the enzyme lysozyme kills bacteria; however, these substances are not present in large enough quantities to eliminate all oral bacteria.

**Salivation**

The secretion of saliva, called **salivation** (sal-i-VÅ-shun), is controlled by the autonomic nervous system. Amounts of saliva secreted daily vary considerably but average 1000–1500 mL (1–1.6 qt). Normally, parasympathetic stimulation promotes continuous secretion of a moderate amount of saliva, which keeps the mucous membranes moist and lubricates the movements of the tongue and lips during speech. The saliva is then swallowed and helps moisten the esophagus. Eventually, most components of saliva are reabsorbed, which prevents fluid loss. Sympathetic stimulation dominates during stress, resulting in dryness of the mouth. If the body becomes dehydrated, the salivary glands stop secreting saliva to conserve water; the resulting dryness of the mouth contributes to the sensation of thirst. Drinking not only restores the homeostasis of body water but also moistens the mouth.

The feel and taste of food also are potent stimulators of salivary gland secretions. Chemicals in the food stimulate receptors in taste buds on the tongue, and impulses are conveyed from the taste buds to two salivary nuclei in the brain stem (superior and inferior salivatory nuclei). Returning parasympathetic impulses in fibers of the facial (VII) and glossopharyngeal (IX) nerves stimulate the secretion of saliva. Saliva continues to be secreted heavily for some time after food is swallowed; this flow of saliva washes out the mouth and dilutes and buffers the remnants of irritating chemicals such as that tasty (but hot!) salsa. The smell, sight, sound, or thought of food may also stimulate secretion of saliva.

---

**CLINICAL CONNECTION**

**Mumps**

Although any of the salivary glands may be the target of a nasopharyngeal infection, the mumps virus (*paramyxovirus*) typically attacks the parotid glands. **Mumps** is an inflammation and enlargement of the parotid glands accompanied by moderate fever, malaise (general discomfort), and extreme pain in the throat, especially when swallowing sour foods or acidic juices. Swelling occurs on one or both sides of the face, just anterior to the ramus of the mandible. In about 30% of males past puberty, the testes may also become inflamed; sterility rarely occurs because testicular involvement is usually unilateral (one testis only). Since a vaccine became available for mumps in 1967, the incidence of the disease has declined dramatically.

---

**Tongue**

The **tongue** is an accessory digestive organ composed of skeletal muscle covered with mucous membrane. Together with its associated muscles, it forms the floor of the oral cavity. The tongue is divided into symmetrical lateral halves by a median septum that extends its entire length, and it is attached inferiorly to the hyoid bone, styloid process of the temporal bone, and mandible. Each half of the tongue consists of an identical complement of extrinsic and intrinsic muscles.

The **extrinsic muscles** of the tongue, which originate outside the tongue (attach to bones in the area) and insert into connective tissues in the tongue, include the **hyoglossus**, **genioglossus**, and **styloglossus muscles** (see Figure 11.7 on page 355). The extrinsic muscles move the tongue from side to side and in and out to maneuver food for chewing, shape the food into a rounded mass, and force the food to the back of the mouth for swallowing. They also form the floor of the mouth and hold the tongue in position. The **intrinsic muscles** originate in and insert into connective tissue within the tongue. They alter the shape and size of the tongue for speech and swallowing. The intrinsic muscles include the **longitudinalis superior**, **longitudinalis inferior**, **transversus linguae**, and **verticalis linguae muscles**. The **lingual frenulum** (lingua = the tongue), a fold of mucous membrane in the midline of the undersurface of the tongue, is attached to the floor of the mouth and aids in limiting the movement of the tongue posteriorly (see Figures 24.5 and 24.6). If a person’s lingual frenulum is abnormally short or rigid—a condition called **ankyloglossia** (ang’-kö-log-LÖ-si-ä)—the person is said to be “tongue-tied” because of the resulting impairment to speech.

The dorsum (upper surface) and lateral surfaces of the tongue are covered with **papillae** (pa-PIL-e = nipple-shaped projections), projections of the lamina propria covered with stratified squamous epithelium (see Figure 17.3 on page 603). Many papillae contain taste buds, the receptors for gustation (taste). Some papillae lack taste buds, but they contain receptors for touch and increase friction between the tongue and food, making it easier for the tongue to move food in the oral cavity. The different types of taste buds are described in detail in Chapter 17. **Lingual glands** in the lamina propria of the tongue secrete both mucus and a watery serous fluid that contains the enzyme **lingual lipase**, which acts on triglycerides.

---

**Teeth**

The **teeth**, or **dentes** (Figure 24.7), are accessory digestive organs located in sockets of the alveolar processes of the mandible and maxillae. The alveolar processes are covered by the **gingivae** (JIN-ji-vē), or gums, which extend slightly into each socket. The sockets are lined by the **periodontal ligament** or membrane (**odont-** = tooth), which consists of dense fibrous connective tissue that anchors the teeth to the socket walls.

A typical tooth has three major external regions: the crown, root, and neck. The **crown** is the visible portion above the level of the gums. Embedded in the socket are one to three **roots**. The **neck** is the constricted junction of the crown and root near the gum line.

Internally, **dentin** forms the majority of the tooth. Dentin consists of a calcified connective tissue that gives the tooth its basic shape and rigidity. It is harder than bone because of its higher content of calcium salts (70% of dry weight).

The dentin of the crown is covered by **enamel**, which consists primarily of calcium phosphate and calcium carbonate. Enamel is also harder than bone because of its even higher content of calcium salts (about 95% of dry weight). In fact, enamel is the hardest substance in the body. It serves to protect the tooth from the wear and tear of chewing. It also protects against acids that
can easily dissolve dentin. The dentin of the root is covered by cementum, another bone-like substance, which attaches the root to the periodontal ligament.

The dentin of a tooth encloses a space. The enlarged part of the space, the pulp cavity, lies within the crown and is filled with pulp, a connective tissue containing blood vessels, nerves, and lymphatic vessels. Narrow extensions of the pulp cavity, called root canals, run through the root of the tooth. Each root canal has an opening at its base, the apical foramen, through which blood vessels, lymphatic vessels, and nerves extend. The blood vessels bring nourishment, the lymphatic vessels offer protection, and the nerves provide sensation.

The branch of dentistry that is concerned with the prevention, diagnosis, and treatment of diseases that affect the pulp, root, periodontal ligament, and alveolar bone is known as endodontics (en'-dö-DON-tiks; endo- = within). Orthodontics (or'-thô-DON-tiks; ortho- = straight) is a branch of dentistry that is concerned with the prevention and correction of abnormally aligned teeth; periodontics (per'-ë-Ö-DON-tiks) is a branch of dentistry concerned with the treatment of abnormal conditions of the tissues immediately surrounding the teeth, such as gingivitis (gum disease).

Humans have two dentitions, or sets of teeth: deciduous and permanent. The first of these—the deciduous teeth (decidu- = falling out), also called primary teeth, milk teeth, or baby teeth—begin to erupt at about 6 months of age, and approximately two teeth appear each month thereafter, until all 20 are present (Figure 24.8a). The incisors, which are closest to the midline, are chisel-shaped and adapted for cutting into food. They are referred to as either central or lateral incisors based on their position. Next to the incisors, moving posteriorly, are the cuspsids (canines), which have a pointed surface called a cusp. Cuspid are used to tear and shred food. Incisors and cuspid have only one root apiece. Posterior to the cuspid lies the first and second molars, which have four cusps. Maxillary (upper) molars have three roots; mandibular (lower) molars have two roots. The molars crush and grind food to prepare it for swallowing.

All the deciduous teeth are lost—generally between ages 6 and 12 years—and are replaced by the permanent (secondary) teeth (Figure 24.8b). The permanent dentition contains 32 teeth that erupt between age 6 and adulthood. The pattern resembles the deciduous dentition, with the following exceptions. The deciduous molars are replaced by the first and second premolars (bicuspids), which have two cusps and one root (upper first premolars have two roots) and are used for crushing and grinding. The permanent molars, which erupt into the mouth posterior to the premolars, do not replace any deciduous teeth and erupt as the jaw grows to accommodate them—the first molars at age 6 (six-year molars), the second molars at age 12 (twelve-year molars), and the third molars (wisdom teeth) after age 17 or not at all.

Often the human jaw does not have enough room posterior to the second molars to accommodate the eruption of the third molars. In this case, the third molars remain embedded in the alveolar bone and are said to be impacted. They often cause pressure and pain and must be removed surgically. In some people, third molars may be dwarfed in size or may not develop at all.

**CLINICAL CONNECTION**  **Root Canal Therapy**

Root canal therapy is a multistep procedure in which all traces of pulp tissue are removed from the pulp cavity and root canals of a badly diseased tooth. After a hole is made in the tooth, the root canals are filled out and irrigated to remove bacteria. Then, the canals are treated with medication and sealed tightly. The damaged crown is then repaired.

**Mechanical and Chemical Digestion in the Mouth**

Mechanical digestion in the mouth results from chewing, or mastication (mas'-ti-KA-shun = to chew), in which food is manipulated by the tongue, ground by the teeth, and mixed with saliva. As a result, the food is reduced to a soft, flexible, easily
swallowed mass called a \textit{bolus} (= lump). Food molecules begin to dissolve in the water in saliva, an important activity because enzymes can react with food molecules in a liquid medium only.

Two enzymes, salivary amylase and lingual lipase, contribute to chemical digestion in the mouth. \textit{Salivary amylase}, which is secreted by the salivary glands, initiates the breakdown of starch. Dietary carbohydrates are either monosaccharide and disaccharide sugars or complex polysaccharides such as starches. Most of the carbohydrates we eat are starches, but only monosaccharides can be absorbed into the bloodstream. Thus, ingested disaccharides and starches must be broken down into monosaccharides. The function of salivary amylase is to begin starch digestion by breaking down starch into smaller molecules such as the disaccharide maltose, the trisaccharide maltotriose, and short-chain glucose polymers called \textit{\greek{alpha}}-dextrins. Even though food is usually swallowed too quickly for all the starches to be broken down in the mouth, salivary amylase in the swallowed food continues to act on the starches for about another hour, at which time stomach acids inactivate it. Saliva also contains \textit{lingual lipase}, which is secreted by lingual glands in the tongue. This enzyme becomes activated in the acidic environment of the stomach and thus starts to work after food is swallowed. It breaks down dietary triglycerides into fatty acids and diglycerides. A diglyceride consists of a glycerol molecule that is attached to two fatty acids.

Table 24.1 summarizes the digestive activities in the mouth.

\textbf{Figure 24.8} Dentitions and times of eruptions (indicated in parentheses). A designated letter (deciduous teeth) or number (permanent teeth) uniquely identifies each tooth. Deciduous teeth begin to erupt at 6 months of age, and approximately two teeth appear each month thereafter, until all 20 are present. (See Tortora, \textit{A Photographic Atlas of the Human Body, Second Edition}, Figure 12.7.)

There are 20 teeth in a complete deciduous set and 32 teeth in a complete permanent set.

\textbf{? Which permanent teeth do not replace any deciduous teeth?}
Chapter 24 • The Digestive System

Checkpoint

10. What structures form the mouth (oral cavity)?
11. How are the major salivary glands distinguished on the basis of location?
12. How is the secretion of saliva regulated?
13. What functions do incisors, cuspids, premolars, and molars perform?

Pharynx

Objective

• Describe the location and function of the pharynx.

When food is first swallowed, it passes from the mouth into the pharynx (= throat), a funnel-shaped tube that extends from the internal nares to the esophagus posteriorly and to the larynx anteriorly (see Figure 23.4 on page 880). The pharynx is composed of skeletal muscle and lined by mucous membrane, and is divided into three parts: the nasopharynx, the oropharynx, and the laryngopharynx. The nasopharynx functions only in respiration, but both the oropharynx and laryngopharynx have digestive as well as respiratory functions.

Swallowed food passes from the mouth into the oropharynx and laryngopharynx; the muscular contractions of these areas help propel food into the esophagus and then into the stomach.

Checkpoint

14. To which two organ systems does the pharynx belong?

Esophagus

Objective

• Describe the location, anatomy, histology, and functions of the esophagus.

The esophagus (e-SOF-a-gus = eating gullet) is a collapsible muscular tube, about 25 cm (10 in.) long, that lies posterior to the trachea. The esophagus begins at the inferior end of the laryngopharynx and passes through the mediastinum anterior to the vertebral column. Then it pierces the diaphragm through an opening called the esophageal hiatus, and ends in the superior portion of the stomach (see Figure 24.1). Sometimes, part of the stomach protrudes above the diaphragm through the esophageal hiatus. This condition, termed a hiatus hernia (HER-nē-a), is described on page 971.

Figure 24.9 Histology of the esophagus. A higher-magnification view of nonkeratinized stratified squamous epithelium is shown in Table 4.1F on page 118. (See Tortora, A Photographic Atlas of the Human Body, Second Edition, Figure 12.8a.)

The esophagus secretes mucus and transports food to the stomach.

Checkpoint

In which layers of the esophagus are the glands that secrete lubricating mucus located?
Histology of the Esophagus

The mucosa of the esophagus consists of nonkeratinized stratified squamous epithelium, lamina propria (areolar connective tissue), and a muscularis mucosae (smooth muscle) (Figure 24.9 on page 934). Near the stomach, the mucosa of the esophagus also contains mucous glands. The stratified squamous epithelium associated with the lips, mouth, tongue, oropharynx, laryngopharynx, and esophagus affords considerable protection against abrasion and wear-and-tear from food particles that are chewed, mixed with secretions, and swallowed. The submucosa contains areolar connective tissue, blood vessels, and mucous glands. The muscularis of the superior third of the esophagus is skeletal muscle, the intermediate third is skeletal and smooth muscle, and the inferior third is smooth muscle. At each end of the esophagus, the muscularis becomes slightly more prominent and forms two sphincters—the upper esophageal sphincter (UES) (e-sof’-a-JÉ-al), which consists of skeletal muscle, and the lower esophageal sphincter (LES), which consists of smooth muscle. The upper esophageal sphincter regulates the movement of food from the pharynx into the esophagus; the lower esophageal sphincter regulates the movement of food from the esophagus into the stomach. The superficial layer of the esophagus is known as the adventitia (ad-ven-TISH-a), rather than the serosa as in the stomach and intestines, because the areolar connective tissue of this layer is not covered by mesothelium and because the connective tissue merges with the connective tissue of surrounding structures of the mediastinum through which it passes. The adventitia attaches the esophagus to surrounding structures.

Physiology of the Esophagus

The esophagus secretes mucus and transports food into the stomach. It does not produce digestive enzymes, and it does not carry on absorption.

CHECKPOINT

15. Describe the location and histology of the esophagus. What is its role in digestion?
16. What are the functions of the upper and lower esophageal sphincters?

DEGLUTITION

OBJECTIVE

• Describe the three phases of deglutition.

The movement of food from the mouth into the stomach is achieved by the act of swallowing, or deglutition (dé-gloo-TISH-un) (Figure 24.10). Deglutition is facilitated by the secretion of saliva and mucus and involves the mouth, pharynx, and esophagus. Swallowing occurs in three stages: (1) the voluntary stage, in which the bolus is passed into the oropharynx; (2) the pharyngeal stage, the involuntary passage of the bolus through the pharynx into the esophagus; and (3) the esophageal stage, the involuntary passage of the bolus through the esophagus into the stomach.

Swallowing starts when the bolus is forced to the back of the oral cavity and into the oropharynx by the movement of the tongue upward and backward against the palate; these actions

Figure 24.10 Deglutition (swallowing). During the pharyngeal stage of deglutition (b) the tongue rises against the palate, the nasopharynx is closed off, the larynx rises, the epiglottis seals off the larynx, and the bolus is passed into the esophagus. During the esophageal stage of deglutition (c), food moves through the esophagus into the stomach via peristalsis.

Deglutition is a mechanism that moves food from the mouth into the stomach.
CHECKPOINT

17. What does deglutition mean?

18. What occurs during the voluntary and pharyngeal phases of swallowing?

19. Does peristalsis “push” or “pull” food along the gastrointestinal tract?

constitute the voluntary stage of swallowing. With the passage of the bolus into the oropharynx, the involuntary pharyngeal stage of swallowing begins (Figure 24.10b). The bolus stimulates receptors in the oropharynx, which send impulses to the deglutition center in the medulla oblongata and lower pons of the brain stem. The returning impulses cause the soft palate and uvula to move upward to close off the nasopharynx, which prevents swallowed foods and liquids from entering the nasal cavity. In addition, the epiglottis closes off the opening to the larynx, which prevents the bolus from entering the rest of the respiratory tract. The bolus moves through the oropharynx and the laryngopharynx. Once the upper esophageal sphincter relaxes, the bolus moves into the esophagus.

The esophageal stage of swallowing begins once the bolus enters the esophagus. During this phase, peristalsis (perˈ-i-STAL-sis; stalsis = constrict), a progression of coordinated contractions and relaxations of the circular and longitudinal layers of the muscularis, pushes the bolus onward (Figure 24.10c). (Peristalsis occurs in other tubular structures, including other parts of the GI tract and the ureters, bile ducts, and uterine tubes; in the esophagus it is controlled by the medulla oblongata.) In the section of the esophagus just superior to the bolus, the circular muscle fibers contract, constricting the esophageal wall and squeezing the bolus toward the stomach. Meanwhile, longitudinal fibers inferior to the bolus also contract, which shortens this inferior section and pushes its walls outward so it can receive the bolus. The contractions are repeated in waves that push the food toward the stomach. As the bolus approaches the end of the esophagus, the lower esophageal sphincter relaxes and the bolus moves into the stomach. Mucus secreted by esophageal glands lubricates the bolus and reduces friction. The passage of solid or semisolid food from the mouth to the stomach takes 4 to 8 seconds; very soft foods and liquids pass through in about 1 second.

Table 24.2 summarizes the digestive activities of the pharynx and esophagus.

<th>CLINICAL CONNECTION</th>
<th>Gastroesophageal Reflux Disease</th>
</tr>
</thead>
<tbody>
<tr>
<td>If the lower esophageal sphincter fails to close adequately after food has entered the stomach, the stomach contents can reflux (back up) into the inferior portion of the esophagus. This condition is known as gastroesophageal reflux disease (GERD). Hydrochloric acid (HCl) from the stomach contents can irritate the esophageal wall, resulting in a burning sensation that is called heartburn because it is experienced in a region very near the heart; it is unrelated to any cardiac problem. Drinking alcohol and smoking can cause the sphincter to relax, worsening the problem. The symptoms of GERD often can be controlled by avoiding foods that strongly stimulate stomach acid secretion (coffee, chocolate, tomatoes, fatty foods, orange juice, peppermint, spearmint, and onions). Other acid-reducing strategies include taking over-the-counter histamine-2 (H2) blockers such as Tagamet HB® or Pepcid AC® 30 to 60 minutes before eating to block acid secretion, and neutralizing acid that has already been secreted with antacids such as Tums® or Maalox®. Symptoms are less likely to occur if food is eaten in smaller amounts and if the person does not lie down immediately after a meal. GERD may be associated with cancer of the esophagus.</td>

STOMACH

**OBJECTIVE**
- Describe the location, anatomy, histology, and functions of the stomach.

The stomach is a J-shaped enlargement of the GI tract directly inferior to the diaphragm in the epigastric, umbilical, and left hypochondriac regions of the abdomen (see Figure 1.12a on page 20). The stomach connects the esophagus to the duodenum, the first part of the small intestine (Figure 24.11). Because a meal can be eaten much more quickly than the intestines can digest and absorb it, one of the functions of the stomach is to serve as a mixing chamber and holding reservoir. At appropriate intervals after food is ingested, the stomach forces a small quantity of material into the first portion of the small intestine. The position and size of the stomach vary continually; the diaphragm pushes it inferiorly with each inhalation and pulls it superiority with each exhalation. Empty, it is about the size of a large sausage, but it is the most distensible part of the GI tract and can accommodate a large quantity of food. In the stomach, digestion of starch continues, digestion of proteins and triglycerides begins, the semisolid bolus is converted to a liquid, and certain substances are absorbed.

**Anatomy of the Stomach**

The stomach has four main regions: the cardia, fundus, body, and pylorus (Figure 24.11). The **cardia** (CAR-de-a) surrounds the superior opening of the stomach. The rounded portion superior to and to the left of the cardia is the **fundus** (FUN-dus). Inferior to the fundus is the large central portion of the stomach, called the **body**. The region of the stomach that connects to the duodenum is the **pylorus** (pi-LOR-us; pyl- = gate; -orus = guard); it has two parts, the **pyloric antrum** (AN-trum = cave), which connects to the body of the stomach, and the **pyloric canal**, which leads into the duodenum. When the stomach is empty, the mucosa lies in large folds, called **rugae** (ROO-gë = wrinkles), that can be seen with the unaided eye. The pylorus communicates with the duodenum of the small intestine via a smooth muscle sphincter called the **pyloric sphincter**. The concave medial border of the stomach is called the **lesser curvature**, and the convex lateral border is called the **greater curvature**.

**Histology of the Stomach**

The stomach wall is composed of the same basic layers as the rest of the GI tract, with certain modifications. The surface of the **mucosa** is a layer of simple columnar epithelial cells called **surface mucous cells** (Figure 24.12b on page 940). The mucosa contains a **lamina propria** (areolar connective tissue) and a **muscularis mucosae** (smooth muscle) (Figure 24.12b). Epithelial cells extend down into the lamina propria, where they form columns of secretory cells called **gastric glands**. Several gastric glands open into the bottom of narrow channels called **gastric pits**. Secretions from several gastric glands flow into each gastric pit and then into the lumen of the stomach.

The gastric glands contain three types of **exocrine gland cells** that secrete their products into the stomach lumen: mucous neck cells, chief cells, and parietal cells. Both surface mucous cells and **mucous neck cells** secrete mucus (Figure 24.12b). **Parietal cells** produce intrinsic factor (needed for absorption of vitamin B₁₂) and hydrochloric acid. The **chief cells** secrete pepsinogen and gastric lipase. The secretions of the mucous, parietal, and chief cells form **gastric juice**, which totals 2000–3000 mL (roughly 2–3 qt.) per day. In addition, gastric glands include a type of enteroeendocrine cell, the **G cell**, which is located mainly in the pyloric antrum and secretes the hormone gastrin into the bloodstream. As we will see shortly, this hormone stimulates several aspects of gastric activity.

Three additional layers lie deep to the mucosa. The **submucosa** of the stomach is composed of areolar connective tissue.
Figure 24.11 **External and internal anatomy of the stomach.** (See Tortora, *A Photographic Atlas of the Human Body, Second Edition*, Figure 12.9.)

The four regions of the stomach are the cardia, fundus, body, and pylorus.

**Functions of the Stomach**
1. Mixes saliva, food, and gastric juice to form chyme.
2. Serves as a reservoir for food before release into small intestine.
3. Secretes gastric juice, which contains HCl (kills bacteria and denatures protein), pepsin (begins the digestion of proteins), intrinsic factor (aids absorption of vitamin B₁₂), and gastric lipase (aids digestion of triglycerides).
4. Secretes gastrin into blood.

*After a very large meal, does your stomach still have rugae?*
The muscularis has three layers of smooth muscle (rather than the two found in the esophagus and small and large intestines): an outer longitudinal layer, a middle circular layer, and an inner oblique layer. The oblique layer is limited primarily to the body of the stomach. The serosa is composed of simple squamous epithelium (mesothelium) and areolar connective tissue; the portion of the serosa covering the stomach is part of the visceral peritoneum. At the lesser curvature of the stomach, the visceral peritoneum extends upward to the liver as the lesser omentum. At the greater curvature of the stomach, the visceral peritoneum continues downward as the greater omentum and drapes over the intestines.

**Mechanical and Chemical Digestion in the Stomach**

Several minutes after food enters the stomach, gentle, rippling, peristaltic movements called mixing waves pass over the stomach every 15 to 25 seconds. These waves macerate food, mix it with secretions of the gastric glands, and reduce it to a soupy liquid called chyme (KI¯M = juice). Few mixing waves are observed in the fundus, which primarily has a storage function. As digestion proceeds in the stomach, more vigorous mixing waves begin at the body of the stomach and intensify as they reach the pylorus. The pyloric sphincter normally remains almost, but not completely, closed. As food reaches the pylorus, each mixing wave periodically forces about 3 mL of chyme into the duodenum through the pyloric sphincter, a phenomenon known as gastric emptying. Most of the chyme is forced back into the body of the stomach, where mixing continues. The next wave pushes the chyme forward again and forces a little more into the duodenum. These forward and backward movements of the gastric contents are responsible for most mixing in the stomach.

Foods may remain in the fundus for about an hour without becoming mixed with gastric juice. During this time, digestion by salivary amylase continues. Soon, however, the churning action mixes chyme with acidic gastric juice, inactivating salivary amylase and activating lingual lipase, which starts to digest triglycerides into fatty acids and diglycerides.

Although parietal cells secrete hydrogen ions (H⁺) and chloride ions (Cl⁻) separately into the stomach lumen, the net effect

---

**Figure 24.12 Histology of the stomach.**

Gastric juice is the combined secretions of mucous cells, parietal cells, and chief cells.
Where is HCl secreted, and what are its functions?
is secretion of hydrochloric acid (HCl). **Proton pumps** powered by \( H^+/K^+ \) ATPases actively transport \( H^+ \) into the lumen while bringing potassium ions \( (K^+) \) into the cell (Figure 24.13). At the same time, \( Cl^- \) and \( K^+ \) diffuse out into the lumen through \( Cl^- \) and \( K^+ \) channels in the apical membrane. The enzyme **carbonic anhydrase**, which is especially plentiful in parietal cells, catalyzes the formation of carbonic acid \( (H_2CO_3) \) from water \( (H_2O) \) and carbon dioxide \( (CO_2) \). As carbonic acid dissociates, it provides a ready source of \( H^+ \) ions. As \( HCO_3^- \) builds up in the cytosol, it exits the parietal cell in exchange for \( Cl^- \) and \( H^+ \) via \( Cl^-/H^+ \) antiporters in the basolateral membrane (next to the lamina propria). \( HCO_3^- \) diffuses into nearby blood capillaries. This “alkaline tide” of bicarbonate ions entering the bloodstream after a meal may be large enough to elevate blood pH slightly and make urine more alkaline.

HCl secretion by parietal cells can be stimulated by several sources: acetylcholine (ACh) released by parasympathetic neurons, gastrin secreted by G cells, and histamine, which is a paracrine substance released by mast cells in the nearby lamina propria. Acetylcholine and gastrin stimulate parietal cells to secrete more HCl in the presence of histamine. In other words, histamine acts synergistically, enhancing the effects of acetylcholine and gastrin. Receptors for all three substances are present in the plasma membrane of parietal cells. The histamine receptors on parietal cells are called \( H_2 \) receptors; they mediate different responses than do the \( H_1 \) receptors involved in allergic responses.

The strongly acidic fluid of the stomach kills many microbes in food. HCl partially denatures (unfolds) proteins in food and stimulates the secretion of hormones that promote the flow of bile and pancreatic juice. Enzymatic digestion of proteins also begins in the stomach. The only proteolytic (protein-digesting) enzyme in the stomach is **pepsin**, which is secreted by chief cells. Pepsin severs certain peptide bonds between amino acids, breaking down a protein chain of many amino acids into smaller peptide fragments. Pepsin is most effective in the very acidic environment of the stomach (pH 2); it becomes inactive at a higher pH.

What keeps pepsin from digesting the protein in stomach cells along with the food? First, pepsin is secreted in an inactive form called **pepsinogen**; in this form, it cannot digest the proteins in the chief cells that produce it. Pepsinogen is not converted into active pepsin until it comes in contact with hydrochloric acid secreted by parietal cells or active pepsin molecules. Second, the stomach epithelial cells are protected from gastric juices by a 1–3 mm thick layer of alkaline mucus secreted by surface mucous cells and mucous neck cells.

Another enzyme of the stomach is **gastric lipase**, which splits the short-chain triglycerides in fat molecules (such as those found in milk) into fatty acids and monoglycerides. A monoglyceride consists of a glycerol molecule that is attached to one fatty acid molecule. This enzyme, which has a limited role in the adult stomach, operates best at a pH of 5–6. More important than either lingual lipase or gastric lipase is pancreatic lipase, an enzyme secreted by the pancreas into the small intestine.

Only a small amount of nutrients are absorbed in the stomach because its epithelial cells are impermeable to most materials. However, mucous cells of the stomach absorb some water, ions, and short-chain fatty acids, as well as certain drugs (especially aspirin) and alcohol.

Within 2 to 4 hours after eating a meal, the stomach has emptied its contents into the duodenum. Foods rich in carbohydrate spend the least time in the stomach; high-protein foods remain somewhat longer, and emptying is slowest after a fat-laden meal containing large amounts of triglycerides.

Table 24.3 summarizes the digestive activities of the stomach.

**CHECKPOINT**

20. Compare the epithelium of the esophagus with that of the stomach. How is each adapted to the function of the organ?

21. What is the importance of rugae, surface mucous cells, mucous neck cells, chief cells, parietal cells, and G cells in the stomach?

22. What is the role of pepsin? Why is it secreted in an inactive form?

23. What are the functions of gastric lipase and lingual lipase in the stomach?

**PANCREAS**

**OBJECTIVE**

• Describe the location, anatomy, histology, and function of the pancreas.

From the stomach, chyme passes into the small intestine. Because chemical digestion in the small intestine depends on activities of the pancreas, liver, and gallbladder, we first consider the activities of these accessory digestive organs and their contributions to digestion in the small intestine.

**Anatomy of the Pancreas**

The pancreas (pan- = all; -creas = flesh), a retroperitoneal gland that is about 12–15 cm (5–6 in.) long and 2.5 cm (1 in.) thick, lies posterior to the greater curvature of the stomach. The pancreas consists of a head, a body, and a tail and is usually connected to the duodenum by two ducts (Figure 24.14a). The head is the expanded portion of the organ near the curve of the duodenum; superior to and to the left of the head are the central body and the tapering tail.

Pancreatic juices are secreted by exocrine cells into small ducts that ultimately unite to form two larger ducts, the pancreatic duct and the accessory duct. These in turn convey the secretions into the small intestine. The pancreatic duct (duct of Wirsung) is the larger of the two ducts. In most people, the pancreatic duct joins the common bile duct from the liver and gallbladder and enters the duodenum as a dilated common duct called the hepatopancreatic ampulla (ampulla of Vater). The ampulla opens on an elevation of the duodenal mucosa known as the major duodenal papilla, which lies about 10 cm (4 in.) inferior to the pyloric sphincter of the stomach. The passage of pancreatic juice and bile through the hepatopancreatic
Figure 24.14 Relation of the pancreas to the liver, gallbladder, and duodenum. The inset shows details of the common bile duct and pancreatic duct forming the hepatopancreatic ampulla (ampulla of Vater) and emptying into the duodenum. (See Tortora, A Photographic Atlas of the Human Body, Second Edition, Figures 12.10, 12.11.)

Pancreatic enzymes digest starches (polysaccharides), proteins, triglycerides, and nucleic acids.
ampulla into the small intestine is regulated by a mass of smooth muscle known as the sphincter of the hepatopancreatic ampulla (sphincter of Oddi). The other major duct of the pancreas, the accessory duct (duct of Santorini), leads from the pancreas and empties into the duodenum about 2.5 cm (1 in.) superior to the hepatopancreatic ampulla.

Histology of the Pancreas

The pancreas is made up of small clusters of glandular epithelial cells. About 99% of the clusters, called acini (AS-i-nē), constitute the exocrine portion of the organ (see Figure 18.18b, c on page 670). The cells within acini secrete a mixture of fluid and digestive enzymes called pancreatic juice. The remaining 1% of the clusters, called pancreatic islets (islets of Langerhans), form the endocrine portion of the pancreas. These cells secrete the hormones glucagon, insulin, somatostatin, and pancreatic polypeptide. The functions of these hormones are discussed in Chapter 18.

Composition and Functions of Pancreatic Juice

Each day the pancreas produces 1200–1500 mL (about 1.2–1.5 qt) of pancreatic juice, a clear, colorless liquid consisting mostly of water, some salts, sodium bicarbonate, and several enzymes. The sodium bicarbonate gives pancreatic juice a slightly alkaline pH (7.1–8.2) that buffers acidic gastric juice in chyme, stops the action of pepsin from the stomach, and creates the proper pH for the action of digestive enzymes in the small intestine. The enzymes in pancreatic juice include a starch-digesting enzyme called pancreatic amylase; several protein-digesting enzymes called trypsin (TRIP-sin), chymotrypsin (ki′-mō-TRIP-sin), carboxypeptidase (kar-bok′-sē-PEP-ti-dās), and elastase (e-LAS-tās); the principal triglyceride-digesting enzyme in adults, called pancreatic lipase; and nucleic acid-digesting enzymes called ribonuclease and deoxyribonuclease.

The protein-digesting enzymes of the pancreas are produced in an inactive form just as pepsin is produced in the stomach as pepsinogen. Because they are inactive, the enzymes do not digest cells of the pancreas itself. Trypsin is secreted in an inactive form called trypsinogen (trip-SIN-ō-jen). Pancreatic acinar cells also secrete a protein called trypsin inhibitor that combines with any trypsin formed accidentally in the pancreas or in pancreatic juice and blocks its enzymatic activity. When trypsinogen reaches the lumen of the small intestine, it encounters an activating brush-border enzyme called enterokinase (en′-ter-ō-KI-nās), which splits off part of the trypsinogen molecule to form trypsin. In turn, trypsin acts on the inactive precursors (called chymotrypsinogen, procarboxypeptidase, and proelastase) to produce chymotrypsin, carboxypeptidase, and elastase, respectively.

**CLINICAL CONNECTION Pancreatitis and Pancreatic Cancer**

Inflammation of the pancreas, as may occur in association with alcohol abuse or chronic gallstones, is called pancreatitis (pan′-krē-a-TI-tis). In a more severe condition known as acute pancreatitis, which is associated with heavy alcohol intake or biliary tract obstruction, the pancreatic cells may release either trypsin instead of trypsinogen or insufficient amounts of trypsin inhibitor, and the trypsin begins to digest the pancreatic cells. Patients with acute pancreatitis usually respond to treatment, but recurrent attacks are the rule. In some people pancreatitis is idiopathic, meaning that the cause is unknown. Other causes of pancreatitis include cystic fibrosis, high levels of calcium in the blood (hypercalcemia), high levels of blood fats (hyperlipidemia or hypertriglyceridemia), some drugs, and certain autoimmune conditions. However, in roughly 70% of adults with pancreatitis, the cause is alcoholism. Often the first episode happens between ages 30 and 40.

Pancreatic cancer usually affects people over 50 years of age and occurs more frequently in males. Typically, there are few symptoms until the disorder reaches an advanced stage and often not until it has metastasized to other parts of the body such as the lymph nodes, liver, or lungs. The disease is nearly always fatal and is the fourth most common cause of death from cancer in the United States. Pancreatic cancer has been linked to fatty foods, high alcohol consumption, genetic factors, smoking, and chronic pancreatitis.
CHECKPOINT

24. Describe the duct system connecting the pancreas to the duodenum.
25. What are pancreatic acini? How do their functions differ from those of the pancreatic islets (islets of Langerhans)?
26. What are the digestive functions of the components of pancreatic juice?

LIVER AND GALLBLADDER

OBJECTIVE

• Describe the location, anatomy, histology, and functions of the liver and gallbladder.

The liver is the heaviest gland of the body, weighing about 1.4 kg (about 3 lb) in an average adult. Of all of the organs of the body, it is second only to the skin in size. The liver is inferior to the diaphragm and occupies most of the right hypochondriac and part of the epigastric regions of the abdominopelvic cavity (see Figure 1.12a on page 20).

The gallbladder (gall- = bile) is a pear-shaped sac that is located in a depression of the posterior surface of the liver. It is 7–10 cm (3–4 in.) long and typically hangs from the anterior inferior margin of the liver (Figure 24.14a).

Anatomy of the Liver and Gallbladder

The liver is almost completely covered by visceral peritoneum and is completely covered by a dense irregular connective tissue layer that lies deep to the peritoneum. The liver is divided into two principal lobes—a large right lobe and a smaller left lobe—by the falciform ligament, a fold of the mesentery (Figure 24.14a). Although the right lobe is considered by many anatomists to include an inferior quadrate lobe and a posterior caudate lobe, based on internal morphology (primarily the distribution of blood vessels), the quadrate and caudate lobes more appropriately belong to the left lobe. The falciform ligament extends from the undersurface of the diaphragm between the two principal lobes of the liver to the superior surface of the liver, helping to suspend the liver in the abdominal cavity. In the free border of the falciform ligament is the ligamentum teres (round ligament), a remnant of the umbilical vein of the fetus (see Figure 21.30a, b on page 821); this fibrous cord extends from the liver to the umbilicus. The right and left coronary ligaments are narrow extensions of the parietal peritoneum that suspend the liver from the diaphragm.

The parts of the gallbladder include the broad fundus, which projects inferiorly beyond the inferior border of the liver; the body, the central portion; and the neck, the tapered portion. The body and neck project superiorly.

Histology of the Liver and Gallbladder

Histologically, the liver is composed of several components (Figure 24.15a–c):

1. Hepatocytes (hepat- = liver; -cytes = cell). Hepatocytes are the major functional cells of the liver and perform a wide array of metabolic, secretory, and endocrine functions. These are specialized epithelial cells with 5 to 12 sides that make up about 80% of the volume of the liver. Hepatocytes form complex three-dimensional arrangements called hepatic laminae. The hepatic laminae are plates of hepatocytes one cell thick bordered on either side by the endothelial-lined vascular spaces called hepatic sinusoids. The hepatic laminae are highly branched, irregular structures. Grooves in the cell membranes between neighboring hepatocytes provide spaces for canaliculi (described next) into which the hepatocytes secrete bile. Bile, a yellow, brownish, or olive-green liquid secreted by hepatocytes, serves as both an excretory product and a digestive secretion.

2. Bile canaliculi (kan-a-LIK-0-li = small canals). These are small ducts between hepatocytes that collect bile produced by the hepatocytes. From bile canaliculi, bile passes into bile ducts and then bile ducts. The bile ducts merge and eventually form the larger right and left hepatic ducts, which unite and exit the liver as the common hepatic duct (see Figure 24.14). The common hepatic duct joins the cystic duct (cystic = bladder) from the gallbladder to form the common bile duct. From here, bile enters the small intestine to participate in digestion.

3. Hepatic sinusoids. These are highly permeable blood capillaries between rows of hepatocytes that receive oxygenated blood from branches of the hepatic artery and nutrient-rich deoxygenated blood from branches of the hepatic portal vein. Recall that the hepatic portal vein brings venous blood from the gastrointestinal organs and spleen into the liver. Hepatic sinusoids converge and deliver blood into a central vein. From central veins the blood flows into the hepatic veins, which drain into the inferior vena cava (see Figure 21.28 on page 818). In contrast to blood which flows toward a central vein, bile flows in the opposite direction. Also present in the hepatic sinusoids are fixed phagocytes called stellate reticuloendothelial (Kupffer) cells, which destroy worn-out white and red blood cells, bacteria, and other foreign matter in the venous blood draining from the gastrointestinal tract.

Together, a bile duct, branch of the hepatic artery, and branch of the hepatic vein are referred to as a portal triad (tri = three).

The hepatocytes, bile duct system, and hepatic sinusoids can be organized into anatomical and functional units in three different ways:

1. Hepatic lobule. For years, anatomists described the hepatic lobule as the functional unit of the liver. According to this model, each hepatic lobule is shaped like a hexagon (six-sided structure). Figure 24.15e, left at its center is the central vein, and radiating out from it are rows of hepatocytes and hepatic sinusoids. Located at three corners of the hexagon is a portal triad. This model is based on a description of the liver of adult pigs. In the human liver it is difficult to find such well-defined hepatic lobules surrounded by thick layers of connective tissue.

2. Portal lobule. This model emphasized the exocrine function of the liver, that is, bile secretion. Accordingly, the bile duct of a
CHAPTER 24  •  THE DIGESTIVE SYSTEM

portal triad is taken as the center of the portal lobule. The portal lobule is triangular in shape and is defined by three imaginary straight lines that connect three central veins that are closest to the portal triad (Figure 24.15e, right). This model has not gained widespread acceptance.

3. Hepatic acinus. In recent years, the preferred structural and functional unit of the liver is the hepatic acinus. Each hepatic acinus is an approximately oval mass that includes portions of two neighboring hepatic lobules. The short axis of the hepatic acinus is defined by branches of the portal triad—branches of the hepatic artery, vein, and bile ducts—that run along the border of the hepatic lobules. The long axis of the acinus is defined by two imaginary curved lines, which connect the two central veins closest to the short axis (Figure 24.15e, center). Hepatocytes in the hepatic acinus are arranged in three zones around the short axis, with no sharp boundaries between them (Figure 24.15d). Cells in zone 1 are closest to the branches of the portal triad and the first to receive incoming oxygen, nutrients, and toxins from incoming blood. These cells are the first ones to take up glucose and store it as glycogen after a meal and break down glycogen to glucose during fasting. They are also the first to show morphological changes following bile duct obstruction or exposure to toxic substances. Zone 1 cells are the last ones to die if circulation is impaired and the first ones to regenerate. Cells in zone 3 are farthest from branches of the portal triad and are the last to show the effects of bile obstruction or exposure to toxins, the first ones to show the effects of impaired circulation, and the last ones to regenerate. Zone 3 cells also are the first to show evidence of fat accumulation. Cells in zone 2 have structural and functional characteristics intermediate between the cells in zones 1 and 3.

The hepatic acinus is the smallest structural and functional unit of the liver. Its popularity and appeal are based on the fact that it provides a logical description and interpretation of (1) patterns of glycogen storage and release and (2) toxic effects, degeneration, and regeneration in the three zones of the hepatic acinus relative to the proximity of the zones to branches of the portal triad.

The mucosa of the gallbladder consists of simple columnar epithelium arranged in rugae resembling those of the stomach. The wall of the gallbladder lacks a submucosa. The middle, muscular coat of the wall consists of smooth muscle fibers. Contraction of the smooth muscle fibers ejects the contents of the gallbladder into the cystic duct. The gallbladder’s outer coat is the visceral peritoneum. The functions of the gallbladder are to store and concentrate the bile produced by the liver (up to tenfold) until it is needed in the small intestine. In the concentration process, water and ions are absorbed by the gallbladder mucosa.

Figure 24.15  Histology of the liver.

Histologically, the liver is composed of hepatocytes, bile canaliculi, and hepatic sinusoids.
Which type of cell in the liver is phagocytic?
Jaundice (JAWN-dis = yellowed) is a yellowish coloration of the sclerae (whites of the eyes), skin, and mucous membranes due to a buildup of a yellow compound called bilirubin. After bilirubin is formed from the breakdown of the heme pigment in aged red blood cells, it is transported to the liver, where it is processed and eventually excreted into bile. The three main categories of jaundice are (1) prehepatic jaundice, due to excess production of bilirubin; (2) hepatic jaundice, due to congenital liver disease, cirrhosis of the liver, or hepatitis; and (3) extrahepatic jaundice, due to blockage of bile drainage by gallstones or cancer of the bowel or the pancreas.

Because the liver of a newborn functions poorly for the first week or so, many babies experience a mild form of jaundice called neonatal (physiological) jaundice that disappears as the liver matures. Usually, it is treated by exposing the infant to blue light, which converts bilirubin into substances the kidneys can excrete.

Blood Supply of the Liver

The liver receives blood from two sources (Figure 24.16). From the hepatic artery it obtains oxygenated blood, and from the hepatic portal vein it receives deoxygenated blood containing newly absorbed nutrients, drugs, and possibly microbes and toxins from the gastrointestinal tract (see Figure 21.28 on page 818). Branches of both the hepatic artery and the hepatic portal vein carry blood into liver sinusoids, where oxygen, most of the nutrients, and certain toxic substances are taken up by the hepatocytes. Products manufactured by the hepatocytes and nutrients needed by other cells are secreted back into the blood, which then drains into the central vein and eventually passes into a hepatic vein. Because blood from the gastrointestinal tract passes through the liver as part of the hepatic portal circulation, the liver is often a site for metastasis of cancer that originates in the GI tract.

Role and Composition of Bile

Each day, hepatocytes secrete 800–1000 mL (about 1 qt) of bile, a yellow, brownish, or olive-green liquid. It has a pH of 7.6–8.6 and consists mostly of water, bile salts, cholesterol, a phospholipid called lecithin, bile pigments, and several ions.

The principal bile pigment is bilirubin. The phagocytosis of aged red blood cells liberates iron, globin, and bilirubin (derived from heme) (see Figure 19.5 on page 697). The iron and globin are recycled; the bilirubin is secreted into the bile and is eventually broken down in the intestine. One of its breakdown products—stercobilin—gives feces their normal brown color.

Bile is partially an excretory product and partially a digestive secretion. Bile salts, which are sodium salts and potassium salts of bile acids (mostly chenodeoxycholic acid and cholic acid), play a role in emulsification, the breakdown of large lipid globules into a suspension of small lipid globules. The small lipid globules present a very large surface area that allows pancreatic lipase to more rapidly accomplish digestion of triglycerides. Bile salts also aid in the absorption of lipids following their digestion.

Although hepatocytes continually release bile, they increase production and secretion when the portal blood contains more bile acids; thus, as digestion and absorption continue in the small intestine, bile release increases. Between meals, after most absorption has occurred, bile flows into the gallbladder for storage because the sphincter of the hepatopancreatic ampulla (sphincter of Oddi; see Figure 24.14) closes off the entrance to the duodenum.

CLINICAL CONNECTION | Gallstones

If bile contains either insufficient bile salts or lecithin or excessive cholesterol, the cholesterol may crystallize to form gallstones. As they grow in size and number, gallstones may cause minimal, intermittent, or complete obstruction to the flow of bile from the gallbladder into the duodenum. Treatment consists of using gallstone-dissolving drugs, lithotripsy (shock-wave therapy), or surgery. For people with recurrent gallstones or for whom drugs or lithotripsy is not indicated, cholecystectomy—the removal of the gallbladder and its contents—is necessary. More than half a million cholecystectomies are performed each year in the United States.
Functions of the Liver

In addition to secreting bile, which is needed for absorption of dietary fats, the liver performs many other vital functions:

- **Carbohydrate metabolism.** The liver is especially important in maintaining a normal blood glucose level. When blood glucose is low, the liver can break down glycogen to glucose and release the glucose into the bloodstream. The liver can also convert certain amino acids and lactic acid to glucose, and it can convert other sugars, such as fructose and galactose, into glucose. When blood glucose is high, as occurs just after eating a meal, the liver converts glucose to glycogen and triglycerides for storage.

- **Lipid metabolism.** Hepatocytes store some triglycerides; break down fatty acids to generate ATP; synthesize lipoproteins, which transport fatty acids, triglycerides, and cholesterol to and from body cells; synthesize cholesterol; and use cholesterol to make bile salts.

- **Protein metabolism.** Hepatocytes deaminate (remove the amino group, NH₂, from) amino acids so that the amino acids can be used for ATP production or converted to carbohydrates or fats. The resulting toxic ammonia (NH₃) is then converted into the much less toxic urea, which is excreted in urine. Hepatocytes also synthesize most plasma proteins, such as alpha and beta globulins, albumin, prothrombin, and fibrinogen.

- **Processing of drugs and hormones.** The liver can detoxify substances such as alcohol and excrete drugs such as penicillin, erythromycin, and sulfonamides into bile. It can also chemically alter or excrete thyroid hormones and steroid hormones such as estrogens and aldosterone.

- **Excretion of bilirubin.** As previously noted, bilirubin, derived from the heme of aged red blood cells, is absorbed by the liver from the blood and secreted into bile. Most of the bilirubin in bile is metabolized in the small intestine by bacteria and eliminated in feces.

- **Synthesis of bile salts.** Bile salts are used in the small intestine for the emulsification and absorption of lipids.

- **Storage.** In addition to glycogen, the liver is a prime storage site for certain vitamins (A, B₁₂, D, E, and K) and minerals (iron and copper), which are released from the liver when needed elsewhere in the body.

- **Phagocytosis.** The stellate reticuloendothelial (Kupffer) cells of the liver phagocytize aged red blood cells, white blood cells, and some bacteria.

- **Activation of vitamin D.** The skin, liver, and kidneys participate in synthesizing the active form of vitamin D.

The liver functions related to metabolism are discussed more fully in Chapter 25.

**SMALL INTESTINE**

**OBJECTIVE**

- Describe the location, anatomy, histology, and functions of the small intestine.

Most digestion and absorption of nutrients occur in a long tube called the **small intestine**. Because of this, its structure is specially adapted for these functions. Its length alone provides a large surface area for digestion and absorption, and that area is further increased by circular folds, villi, and microvilli. The small intestine begins at the pyloric sphincter of the stomach, coils through the central and inferior part of the abdominal cavity, and eventually opens into the large intestine. It averages 2.5 cm (1 in.) in diameter; its length is about 3 m (10 ft) in a living person and about 6.5 m (21 ft) in a cadaver due to the loss of smooth muscle tone after death.

**Anatomy of the Small Intestine**

The small intestine is divided into three regions (Figure 24.17). The **duodenum** (doo-ō-DÉ-num), the shortest region, is retroperitoneal. It starts at the pyloric sphincter of the stomach and extends about 25 cm (10 in.) until it merges with the jejunum. **Duodenum** means “12”; it is so named because it is about as long as the width of 12 fingers. The **jejunum** (je-JOO-num) is about 1 m (3 ft) long and extends to the ileum. **Jejunum** means “empty,” which is how it is found at death. The final and longest region of the small intestine, the **ileum** (IL-ē-um = twisted), measures about 2 m (6 ft) and joins the large intestine at a smooth muscle sphincter called the **ileocecal sphincter** (il’-ē-ō-SÉ-kal).

**Histology of the Small Intestine**

The wall of the small intestine is composed of the same four layers that make up most of the GI tract: mucosa, submucosa, muscularis, and serosa (Figure 24.18a on page 951). The **mucosa** is composed of a layer of epithelium, lamina propria, and muscularis mucosae. The epithelial layer of the small intestinal mucosa consists of simple columnar epithelium that contains many types of cells (Figure 24.18b). **Absorptive cells** of the epithelium digest and absorb nutrients in small intestinal chyme. Also present in the epithelium are goblet cells, which secrete mucus. The small intestinal mucosa contains many deep crevices lined with glandular epithelium. Cells lining the crevices form the **intestinal glands** (crypts of Lieberkühn) and secrete intestinal juice (to be discussed shortly). Besides absorptive cells and goblet cells, the intestinal glands also contain paneth cells and
enteroendocrine cells. Paneth cells secrete lysozyme, a bacteriocidal enzyme, and are capable of phagocytosis. Paneth cells may have a role in regulating the microbial population in the small intestine. Three types of enteroendocrine cells are found in the intestinal glands of the small intestine: S cells, CCK cells, and K cells, which secrete the hormones secretin (se-KRÉ-tin), cholecystokinin (kō-le-sis′-tō-KIN-in) or CCK, and glucose-dependent insulinotropic peptide or GIP, respectively.

The lamina propria of the small intestinal mucosa contains areolar connective tissue and has an abundance of mucosa-associated lymphoid tissue (MALT). Solitary lymphatic nodules are most numerous in the distal part of the ileum (Figure 24.19c on page 953). Groups of lymphatic nodules referred to as aggregated lymphatic follicles (Peyer’s patches) are also present in the ileum. The muscularis mucosae of the small intestinal mucosa consists of smooth muscle.

The submucosa of the duodenum contains duodenal (Brunner’s) glands (Figure 24.19a on page 952), which secrete an alkaline mucus that helps neutralize gastric acid in the chyme. Sometimes the lymphatic tissue of the lamina propria extends through the muscularis mucosae into the submucosa. The muscularis of the small intestine consists of two layers of smooth muscle. The outer, thinner layer contains longitudinal fibers; the inner, thicker layer contains circular fibers. Except for a major portion of the duodenum, the serosa (or visceral peritoneum) completely surrounds the small intestine.

Even though the wall of the small intestine is composed of the same four basic layers as the rest of the GI tract, special structural features of the small intestine facilitate the process of digestion and absorption. These structural features include circular folds, villi, and microvilli. Circular folds or plicae circulares are folds of the mucosa and submucosa (see Figure 24.17b). These permanent ridges, which are about 10 mm (0.4 in.) long, begin near the proximal portion of the duodenum and end at about the midportion of the ileum. Some extend all the way around the circumference of the intestine; others extend only part of the way around. Circular folds enhance absorption by increasing surface area and causing the chyme to spiral, rather than move in a straight line, as it passes through the small intestine.

Also present in the small intestine are villi (= tufts of hair), which are fingerlike projections of the mucosa that are 0.5–1 mm long (see Figure 24.18a). The large number of villi (20–40 per square millimeter) vastly increases the surface area of the epithelium available for absorption and digestion and gives the intestinal mucosa a velvety appearance. Each villus (singular form) is covered by epithelium and has a core of lamina propria; embedded in the connective tissue of the lamina

Microvilli

What is the functional significance of the blood capillary network and lacteal in the center of each villus?
Figure 24.19 Histology of the duodenum and ileum.

Microvilli in the small intestine contain several brush-border enzymes that help digest nutrients.
propria are an arteriole, a venule, a blood capillary network, and a lacteal (LAK-tē-al = milky), which is a lymphatic capillary. Nutrients absorbed by the epithelial cells covering the villus pass through the wall of a capillary or a lacteal to enter blood or lymph, respectively.

Besides circular folds and villi, the small intestine also has microvilli (mi-krō-VIL-i; micro- = small), which are projections of the apical (free) membrane of the absorptive cells. Each microvillus is a 1 μm-long cylindrical, membrane-covered projection that contains a bundle of 20–30 actin filaments. When viewed through a light microscope, the microvilli are too small to be seen individually; instead they form a fuzzy line, called the brush border, extending into the lumen of the small intestine (Figure 24.19d). There are an estimated 200 million microvilli per square millimeter of small intestine. Because the microvilli greatly increase the surface area of the plasma membrane, larger amounts of digested nutrients can diffuse into absorptive cells in a given period. The brush border also contains several brush-border enzymes that have digestive functions (discussed shortly).

Role of Intestinal Juice and Brush-Border Enzymes

About 1–2 liters (1–2 qt) of intestinal juice, a clear yellow fluid, are secreted each day. Intestinal juice contains water and mucus and is slightly alkaline (pH 7.6). Together, pancreatic and intestinal juices provide a liquid medium that aids the absorption of substances from chyme in the small intestine. The absorptive cells of the small intestine synthesize several digestive enzymes, called brush-border enzymes, and insert them in the plasma membrane of the microvilli. Thus, some enzymatic digestion occurs at the surface of the absorptive cells that line the villi, rather than in the lumen exclusively, as occurs in other parts of the GI tract. Among the brush-border enzymes are four carbohydrate-digesting enzymes called α-dextrinase, maltase, sucrase, and lactase; protein-digesting enzymes called peptidases (aminopeptidase and dipeptidase); and two types of nucleotide-digesting enzymes, nucleosidases and phosphatases. Also, as absorptive cells slough off into the lumen of the small intestine, they break apart and release enzymes that help digest nutrients in the chyme.

Mechanical Digestion in the Small Intestine

The two types of movements of the small intestine—segmentations and a type of peristalsis called migrating motility complexes—are governed mainly by the myenteric plexus. Segmentations are localized, mixing contractions that occur in portions of intestine distended by a large volume of chyme. Segmentations mix chyme with the digestive juices and bring the particles of food into contact with the mucosa for absorption; they do not push the intestinal contents along the tract. A segmentation starts with the contractions of circular muscle fibers in a portion of the small intestine, an action that constricts the intestine into segments. Next, muscle fibers that encircle the middle of each segment also contract, dividing each segment again. Finally, the fibers that first contracted relax, and each small segment unites with an adjoining small segment so that large segments are formed again. As this sequence of events repeats, the chyme sloshes back and forth. Segmentations occur most rapidly in the duodenum, about 12 times per minute, and progressively slow to about 8 times per minute in the ileum. This movement is similar to alternately squeezing the middle and then the ends of a capped tube of toothpaste.

After most of a meal has been absorbed, which lessens distension of the wall of the small intestine, segmentation stops and peristalsis begins. The type of peristalsis that occurs in the small intestine, termed a migrating motility complex (MMC), begins...
in the lower portion of the stomach and pushes chyme forward along a short stretch of small intestine before dying out. The MMC slowly migrates down the small intestine, reaching the end of the ileum in 90–120 minutes. Then another MMC begins in the stomach. Altogether, chyme remains in the small intestine for 3–5 hours.

**Chemical Digestion in the Small Intestine**

In the mouth, salivary amylase converts starch (a polysaccharide) to maltose (a disaccharide), maltotriose (a trisaccharide), and α-dextrins (short-chain, branched fragments of starch with 5–10 glucose units). In the stomach, pepsin converts proteins to peptides (small fragments of proteins), and lingual and gastric lipases convert some triglycerides into fatty acids, diglycerides, and monoglycerides. Thus, chyme entering the small intestine contains partially digested carbohydrates, proteins, and lipids. The completion of the digestion of carbohydrates, proteins, and lipids is a collective effort of pancreatic juice, bile, and intestinal juice in the small intestine.

**Digestion of Carbohydrates**

Even though the action of **salivary amylase** may continue in the stomach for a while, the acidic pH of the stomach destroys salivary amylase and ends its activity. Thus, only a few starches are broken down by the time chyme leaves the stomach. Those starches not already broken down into maltose, maltotriose, and α-dextrins are cleaved by **pancreatic amylase**, an enzyme in pancreatic juice that acts in the small intestine. Although pancreatic amylase acts on both glycogen and starches, it has no effect on another polysaccharide called cellulose, an indigestible plant fiber that is commonly referred to as “roughage” as its effect on another polysaccharide called cellulose, an indigestible. Amylase acts on both glycogen and starches, it has no effect on another polysaccharide called cellulose, an indigestible plant fiber that is commonly referred to as “roughage” as it acts in the small intestine. After amylase (either salivary or pancreatic) has split starch into smaller fragments, a brush-border enzyme called **α-dextrinase** acts on the resulting α-dextrins, clipping off one glucose unit at a time.

Ingested molecules of sucrose, lactose, and maltose—three disaccharides—are not acted on until they reach the small intestine. Three brush-border enzymes digest the disaccharides into monosaccharides. **Sucrase** breaks sucrose into a molecule of glucose and a molecule of fructose; **lactase** digests lactose into a molecule of glucose and a molecule of galactose; and **maltase** splits maltose and maltotriose into two or three molecules of glucose, respectively. Digestion of carbohydrates ends with the production of monosaccharides, which the digestive system is able to absorb.

**Digestion of Proteins**

Recall that protein digestion starts in the stomach, where proteins are fragmented into peptides by the action of pepsin. Enzymes in pancreatic juice—**trypsin**, **chymotrypsin**, **cathepsin**, **carboxypeptidase**, and **elastase**—continue to break down proteins into peptides. Although all these enzymes convert whole proteins into peptides, their actions differ somewhat because each splits peptide bonds between different amino acids. Trypsin, chymotrypsin, and elastase all cleave the peptide bond between a specific amino acid and its neighbor; carboxypeptidase splits off the amino acid at the carboxyl end of a peptide. Protein digestion is completed by two **peptidases** in the brush border: aminopeptidase and dipeptidase. **Aminopeptidase** cleaves off the amino acid at the amino end of a peptide. **Dipeptidase** splits dipeptides (two amino acids joined by a peptide bond) into single amino acids.

**Digestion of Lipids**

The most abundant lipids in the diet are triglycerides, which consist of a molecule of glycerol bonded to three fatty acid molecules (see Figure 2.17 on page 47). Enzymes that split triglycerides and phospholipids are called **lipases**. Recall that there are three types of lipases that can participate in lipid digestion: **lingual lipase**, **gastric lipase**, and **pancreatic lipase**. Although some lipid digestion occurs in the stomach through the action of lingual and gastric lipases, most occurs in the small intestine through the action of pancreatic lipase. Triglycerides are broken down by pancreatic lipase into fatty acids and monoglycerides. The liberated fatty acids can be either short-chain fatty acids (with fewer than 10–12 carbons) or long-chain fatty acids.

Before a large lipid globule containing triglycerides can be digested in the small intestine, it must first undergo **emulsification**—a process in which the large lipid globule is broken down into several small lipid globules. Recall that bile contains bile salts, the sodium salts and potassium salts of bile acids (mainly chenodeoxycholic acid and cholic acid). Bile salts are **amphipathic**, which means that each bile salt has a hydrophobic (nonpolar) region and a hydrophilic (polar) region. The amphipathic nature of bile salts allows them to emulsify a large lipid globule: The hydrophobic regions of bile salts interact with the large lipid globule, while the hydrophilic regions of bile salts interact with the watery intestinal chyme. Consequently, the large lipid globule is broken apart into several small lipid globules, each about 1 μm in diameter. The small lipid globules...
formed from emulsification provide a large surface area that allows pancreatic lipase to function more effectively.

**Digestion of Nucleic Acids**

Pancreatic juice contains two nucleases: ribonuclease, which digests RNA, and deoxyribonuclease, which digests DNA. The nucleotides that result from the action of the two nucleases are further digested by brush-border enzymes called nucleosidases and phosphatases into pentoses, phosphates, and nitrogenous bases. These products are absorbed via active transport.

Table 24.4 summarizes the sources, substrates, and products of the digestive enzymes.
Absorption in the Small Intestine

All the chemical and mechanical phases of digestion from the mouth through the small intestine are directed toward changing food into forms that can pass through the absorptive epithelial cells lining the mucosa and into the underlying blood and lymphatic vessels. These forms are monosaccharides (glucose, fructose, and galactose) from carbohydrates; single amino acids, dipeptides, and tripeptides from proteins; and fatty acids, glycerol, and monoglycerides from triglycerides. Passage of these digested nutrients from the gastrointestinal tract into the blood or lymph is called absorption.

Absorption of materials occurs via diffusion, facilitated diffusion, osmosis, and active transport. About 90% of all absorption of nutrients occurs in the small intestine; the other 10% occurs in the stomach and large intestine. Any undigested or unabsorbed material left in the small intestine passes on to the large intestine.

Absorption of Monosaccharides

All carbohydrates are absorbed as monosaccharides. The capacity of the small intestine to absorb monosaccharides is huge—an estimated 120 grams per hour. As a result, all dietary carbohydrates that are digested normally are absorbed, leaving only indigestible cellulose and fibers in the feces. Monosaccharides pass from the lumen through the apical membrane via facilitated diffusion or active transport. Fructose, a monosaccharide found in fruits, is transported via facilitated diffusion; glucose and galactose are transported into absorptive cells of the villi via secondary active transport that is coupled to the active transport of Na\(^+\) (Figure 24.20a). The transporter has binding sites for one glucose molecule and two sodium ions; unless all three sites are filled, neither substance is transported. Galactose competes with glucose to ride the same transporter. (Because both Na\(^+\) and glucose or galactose move in the same direction, this is a symporter.) Monosaccharides then move out of the absorptive cells through their basolateral surfaces via facilitated diffusion and enter the capillaries of the villi (see Figure 24.20b).

Absorption of Amino Acids, Dipeptides, and Tripeptides

Most proteins are absorbed as amino acids via active transport processes that occur mainly in the duodenum and jejunum. About half of the absorbed amino acids are present in food; the other half come from the body itself as proteins in digestive juices and dead cells that slough off the mucosal surface! Normally, 95–98% of the protein present in the small intestine is digested and absorbed. Different transporters carry different types of amino acids. Some amino acids enter absorptive cells of the villi via Na\(^+\)-dependent secondary active transport processes that are similar to the glucose transporter; other amino acids are actively transported by themselves. At least one symporter brings in dipeptides and tripeptides together with H\(^+\); the peptides then are hydrolyzed to single amino acids inside the absorptive cells. Amino acids move out of the absorptive cells via diffusion and enter capillaries of the villus (Figure 24.20a). Both monosaccharides and amino acids are transported in the blood to the liver by way of the hepatic portal system. If not removed by hepatocytes, they enter the general circulation.

Absorption of Lipids

All dietary lipids are absorbed via simple diffusion. Adults absorb about 95% of the lipids present in the small intestine; due to their lower production of bile, newborn infants absorb only about 85% of lipids. As a result of their emulsification and digestion, triglycerides are mainly broken down into monoglycerides and fatty acids, which can be either short-chain fatty acids or long-chain fatty acids. Although short-chain fatty acids are hydrophobic, they are very small in size. Because of their size, they can dissolve in the watery intestinal chyme, pass through the absorptive cells via simple diffusion, and follow the same route taken by monosaccharides and amino acids into a blood capillary of a villus (Figure 24.20a). Long-chain fatty acids and monoglycerides are large and hydrophobic and have difficulty being suspended in the watery environment of the intestinal chyme. Besides their role in emulsification, bile salts also help to make these long-chain fatty acids and monoglycerides more soluble. The bile salts in intestinal chyme surround the long-chain fatty acids and monoglycerides, forming tiny spheres called micelles (mi=SEIZ = small morsels), each of which is 2–10 nm in diameter and includes 20–50 bile salt molecules (Figure 24.20a). Micelles are formed due to the amphipathic nature of bile salts: The hydrophobic regions of bile salts interact with the long-chain fatty acids and monoglycerides, and the hydrophilic regions of bile salts interact with the watery intestinal chyme. Once formed, the micelles move from the interior of the small intestinal lumen to the brush border of the absorptive cells. At that point, the long-chain fatty acids and monoglycerides diffuse out of the micelles into the absorptive cells, leaving the micelles behind in the chyme. The micelles continually repeat this ferrying function as they move from the brush border back through the chyme to the interior of the small intestinal lumen to pick up more long-chain fatty acids and monoglycerides. Micelles also solubilize other large hydrophobic molecules such as fat-soluble vitamins (A, D, E, and K) and cholesterol that may be present in intestinal chyme, and aid in their absorption. These fat-soluble vitamins and cholesterol molecules are picked up in the micelles along with the long-chain fatty acids and monoglycerides.

Once inside the absorptive cells, long-chain fatty acids and monoglycerides are recombined to form triglycerides, which aggregate into globules along with phospholipids and cholesterol and become coated with proteins. These large spherical massses—about 80 nm in diameter, are called chylomicrons. Chylomicrons leave the absorptive cell via exocytosis. Because they are so large and bulky, chylomicrons cannot enter blood capillaries—the pores in the walls of blood capillaries are too small. Instead, chylomicrons enter lacteals, which have much larger pores than blood capillaries. From lacteals, chylomicrons are transported by way of lymphatic vessels to the thoracic duct and enter the blood at the left subclavian vein.
Figure 24.20 Absorption of digested nutrients in the small intestine. For simplicity, all digested foods are shown in the lumen of the small intestine, even though some nutrients are digested by brush-border enzymes.

Long-chain fatty acids and monoglycerides are absorbed into lacteals; other products of digestion enter blood capillaries.

?- A monoglyceride may be larger than an amino acid. Why can monoglycerides be absorbed by simple diffusion, but amino acids cannot?
The hydrophilic protein coat that surrounds each chylomicon keeps the chylomicrons suspended in blood and prevents them from sticking to each other.

Within 10 minutes after absorption, about half of the chylomicrons have already been removed from the blood as they pass through blood capillaries in the liver and adipose tissue. This removal is accomplished by an enzyme attached to the apical surface of capillary endothelial cells, called lipoprotein lipase, that breaks down triglycerides in chylomicrons and other lipoproteins into fatty acids and glycerol. The fatty acids diffuse into hepatocytes and adipose cells and combine with glycerol during resynthesis of triglycerides. Two or three hours after a meal, few chylomicrons remain in the blood.

After participating in the emulsification and absorption of lipids, 90–95% of the bile salts are reabsorbed by active transport in the final segment of the small intestine (ileum) and returned by the blood to the liver through the hepatic portal system for recycling. This cycle of bile salt secretion by hepatocytes into bile, reabsorption by the ileum, and resecretion into bile is called the enterohepatic circulation. Insufficient bile salts, due either to obstruction of the bile ducts or removal of the gallbladder, can result in the loss of up to 40% of dietary lipids in feces due to diminished lipid absorption. When lipids are not absorbed properly, the fat-soluble vitamins are not adequately absorbed.

Absorption of Electrolytes

Many of the electrolytes absorbed by the small intestine come from gastrointestinal secretions, and some are part of ingested foods and liquids. Recall that electrolytes are compounds that separate into ions in water and conduct electricity. Sodium ions are actively transported out of absorptive cells by basolateral sodium–potassium pumps (Na+/K+ ATPase) after they have moved into absorptive cells via diffusion and secondary active transport. Thus, most of the sodium ions (Na+) in gastrointestinal secretions are reclaimed and not lost in the feces. Negatively charged bicarbonate, chloride, iodide, and nitrate ions can passively follow Na+ or be actively transported. Calcium ions also are absorbed actively in a process stimulated by calcitriol. Other electrolytes such as iron, potassium, magnesium, and phosphate ions also are absorbed via active transport mechanisms.

Absorption of Vitamins

As you have just learned, the fat-soluble vitamins A, D, E, and K are included with ingested dietary lipids in micelles and are absorbed via simple diffusion. Most water-soluble vitamins, such as most B vitamins and vitamin C, also are absorbed via simple diffusion. Vitamin B12, however, combines with intrinsic factor produced by the stomach, and the combination is absorbed in the ileum via an active transport mechanism.

Absorption of Water

The total volume of fluid that enters the small intestine each day—about 9.3 liters (9.8 qt)—comes from ingestion of liquids (about 2.3 liters) and from various gastrointestinal secretions (about 7.0 liters). Figure 24.21 depicts the amounts of fluid ingested, secreted, absorbed, and excreted by the GI tract. The small intestine absorbs about 8.3 liters of the fluid; the remainder passes into the large intestine, where most of the rest of it—about 0.9 liter—is also absorbed. Only 0.1 liter (100 mL) of water is excreted in the feces each day. Most is excreted via the urinary system.

All water absorption in the GI tract occurs via osmosis from the lumen of the intestines through absorptive cells and into blood capillaries. Because water can move across the intestinal mucosa in both directions, the absorption of water from the small intestine depends on the absorption of electrolytes and nutrients to maintain an osmotic balance with the blood. The absorbed electrolytes, monosaccharides, and amino acids establish a concentration gradient for water that promotes water absorption via osmosis.

Table 24.5 summarizes the digestive activities of the pancreas, liver, gallbladder, and small intestine.

---

**Figure 24.21** Daily volumes of fluid ingested, secreted, absorbed, and excreted from the GI tract.

- All water absorption in the GI tract occurs via osmosis.
**CLINICAL CONNECTION | Absorption of Alcohol**

The intoxicating and incapacitating effects of alcohol depend on the blood alcohol level. Because it is lipid-soluble, alcohol begins to be absorbed in the stomach. However, the surface area available for absorption is much greater in the small intestine than in the stomach, so when alcohol passes into the duodenum, it is absorbed more rapidly. Thus, the longer the alcohol remains in the stomach, the more slowly blood alcohol level rises. Because fatty acids in chyme slow gastric emptying, blood alcohol level will rise more slowly when fat-rich foods, such as pizza, hamburgers, or nachos, are consumed with alcoholic beverages. Also, the enzyme alcohol dehydrogenase, which is present in gastric mucosa cells, breaks down some of the alcohol to acetaldehyde, which is not intoxicating. When the rate of gastric emptying is slower, proportionally more alcohol will be absorbed and converted to acetaldehyde in the stomach, and thus less alcohol will reach the bloodstream. Given identical consumption of alcohol, females often develop higher blood alcohol levels (and therefore experience greater intoxication) than males of comparable size because the activity of gastric alcohol dehydrogenase is up to 60% lower in females than in males. Asian males may also have lower levels of this gastric enzyme.

### CHECKPOINT

32. List the regions of the small intestine and describe their functions.
33. In what ways are the mucosa and submucosa of the small intestine adapted for digestion and absorption?
34. Describe the types of movement that occur in the small intestine.
35. Explain the functions of pancreatic amylase, aminopeptidase, gastric lipase, and deoxyribonuclease.
36. What is the difference between digestion and absorption? How are the end products of carbohydrate, protein, and lipid digestion absorbed?
37. By what routes do absorbed nutrients reach the liver?
38. Describe the absorption of electrolytes, vitamins, and water by the small intestine.

### TABLE 24.5

#### Summary of Digestive Activities in the Pancreas, Liver, Gallbladder, and Small Intestine

### LARGE INTESTINE

#### OBJECTIVE

- Describe the anatomy, histology, and functions of the large intestine.

The large intestine is the terminal portion of the GI tract. The overall functions of the large intestine are the completion of absorption, the production of certain vitamins, the formation of feces, and the expulsion of feces from the body.

#### Anatomy of the Large Intestine

The **large intestine**, which is about 1.5 m (5 ft) long and 6.5 cm (2.5 in.) in diameter, extends from the ileum to the anus. It is attached to the posterior abdominal wall by its **mesocolon**, which is a double layer of peritoneum (see Figure 24.4a). Structurally, the four major regions of the large intestine are the cecum, colon, rectum, and anal canal (Figure 24.22a).

The opening from the ileum into the large intestine is guarded by a fold of mucous membrane called the **ileocecal sphincter (valve)**, which allows materials from the small intestine to pass into the large intestine. Hanging inferior to the ileocecal valve is the **cecum**, a small pouch about 6 cm (2.4 in.) long. Attached to the cecum is a twisted, coiled tube, measuring about 8 cm (3 in.) in length, called the **appendix** or **vermiform appendix** (vermi-form = worm-shaped; appendix = appendage). The mesentry of the appendix, called the **mesoappendix**, attaches the appendix to the inferior part of the mesentery of the ileum.

The open end of the cecum merges with a long tube called the **colon** (= food passage), which is divided into ascending, transverse, descending, and sigmoid portions. Both the ascending and
descending colon are retroperitoneal; the transverse and sigmoid colon are not. True to its name, the ascending colon ascends on the right side of the abdomen, reaches the inferior surface of the liver, and turns abruptly to the left to form the right colic (hepatic) flexure. The colon continues across the abdomen to the left side as the transverse colon. It curves beneath the inferior end of the spleen on the left side as the left colic (splenic) flexure and passes inferiorly to the level of the iliac crest as the descending colon. The sigmoid colon (sigmoid = S-shaped) begins near the left iliac crest, projects medially to the midline, and terminates as the rectum at about the level of the third sacral vertebra.

The rectum, the last 20 cm (8 in.) of the GI tract, lies anterior to the sacrum and coccyx. The terminal 2–3 cm (1 in.) of the rectum is called the anal canal (Figure 24.22b). The mucous membrane of the anal canal is arranged in longitudinal folds called anal columns that contain a network of arteries and veins. The opening of the anal canal to the exterior, called the anus, is guarded by an internal anal sphincter of smooth muscle (involuntary) and an external anal sphincter of skeletal muscle (voluntary). Normally these sphincters keep the anus closed except during the elimination of feces.

### Functions of the Large Intestine

1. Haustral churning, peristalsis, and mass peristalsis drive the contents of the colon into the rectum.
2. Bacteria in the large intestine convert proteins to amino acids, break down amino acids, and produce some B vitamins and vitamin K.
3. Absorbing some water, ions, and vitamins.
4. Forming feces.
5. Defecating (emptying the rectum).

Which portions of the colon are retroperitoneal?
Histology of the Large Intestine

The wall of the large intestine contains the typical four layers found in the rest of the GI tract: mucosa, submucosa, muscularis, and serosa. The **mucosa** consists of simple columnar epithelium, lamina propria (areolar connective tissue), and muscularis mucosae (smooth muscle) (Figure 24.23a). The epithelium contains mostly absorptive and goblet cells (Figure 24.23b, c). The absorptive cells function primarily in water absorption; the goblet cells secrete mucus that lubricates the passage of the colonic contents. Both absorptive and goblet cells are located in long, straight, tubular **intestinal glands** (crypts of Lieberkühn) that extend the full thickness of the mucosa. Solitary lymphatic nodules are also found in the lamina propria of the mucosa and may extend through the muscularis mucosae into the submucosa. Compared to the small intestine, the mucosa of the large intestine does not have as many structural adaptations that increase surface area. There are no circular folds or villi; however, microvilli are present on the absorptive cells.

Consequently, much more absorption occurs in the small intestine than in the large intestine.

The **submucosa** of the large intestine consists of areolar connective tissue. The **muscularis** consists of an external layer of longitudinal smooth muscle and an internal layer of circular smooth muscle. Unlike other parts of the GI tract, portions of the longitudinal muscles are thickened, forming three conspicuous bands called the **teniae coli** (TÉ-nē-è KÖ-Ìí; teniae = flat bands) that run most of the length of the large intestine (see Figure 24.22a). The teniae coli are separated by portions of the wall with less or no longitudinal muscle. Tonic contractions of the bands gather the colon into a series of pouches called **haustra** (HAWS-tra = shaped like pouches; singular is haustrum), which give the colon a puckered appearance. A single layer of circular smooth muscle lies between teniae coli. The **serosa** of the large intestine is part of the visceral peritoneum. Small pouches of visceral peritoneum filled with fat are attached to teniae coli and are called **omentals (fatty)** appendices.

**Clinical Connection** Polyps in the Colon

Polyps in the colon are generally slow-developing benign growths that arise from the mucosa of the large intestine. Often, they do not cause symptoms. If symptoms do occur, they include diarrhea, blood in the feces, and mucus discharged from the anus. The polyps are removed by colonoscopy or surgery because some of them may become cancerous.
Mechanical Digestion in the Large Intestine

The passage of chyme from the ileum into the cecum is regulated by the action of the ileocecal sphincter. Normally, the valve remains partially closed so that the passage of chyme into the cecum usually occurs slowly. Immediately after a meal, a gastroileal reflex intensifies peristalsis in the ileum and forces any chyme into the cecum. The hormone gastrin also relaxes the sphincter. Whenever the cecum is distended, the degree of contraction of the ileocecal sphincter intensifies.

What is the function of the goblet cells in the large intestine?
Movements of the colon begin when substances pass the ileocecal sphincter. Because chyme moves through the small intestine at a fairly constant rate, the time required for a meal to pass into the colon is determined by gastric emptying time. As food passes through the ileocecal sphincter, it fills the cecum and accumulates in the ascending colon.

One movement characteristic of the large intestine is **hastral churning**. In this process, the haustra remain relaxed and become distended while they fill up. When the distension reaches a certain point, the walls contract and squeeze the contents into the next haustrum. **Peristalsis** also occurs, although at a slower rate (3–12 contractions per minute) than in more proximal portions of the tract. A final type of movement is **mass peristalsis**, a strong peristaltic wave that begins at about the middle of the transverse colon and quickly drives the contents of the colon into the rectum. Because food in the stomach initiates this **gastrocolic reflex** in the colon, mass peristalsis usually takes place three or four times a day, during or immediately after a meal.

**Chemical Digestion in the Large Intestine**

The final stage of digestion occurs in the colon through the activity of bacteria that inhabit the lumen. Mucus is secreted by the glands of the large intestine, but no enzymes are secreted. Chyme is prepared for elimination by the action of bacteria, which ferment any remaining carbohydrates and release hydrogen, carbon dioxide, and methane gases. These gases contribute to flatulence (gas) in the colon, termed **flatulence** when it is excessive. Bacteria also convert any remaining proteins to amino acids and break down the amino acids into simpler substances: indole, skatole, hydrogen sulfide, and fatty acids. Some of the indole and skatole is eliminated in the feces and contributes to their odor; the rest is absorbed and transported to the liver, where these compounds are converted to less toxic compounds and excreted in the urine. Bacteria also decompose bilirubin to simpler pigments, including stercobilin, which gives feces their brown color. Bacterial products that are absorbed in the colon include several vitamins needed for normal metabolism, among them some B vitamins and vitamin K.

**Absorption and Feces Formation in the Large Intestine**

By the time chyme has remained in the large intestine 3–10 hours, it has become solid or semisolid because of water absorption and is now called **feces**. Chemically, feces consist of water, inorganic salts, sloughed-off epithelial cells from the mucosa of the gastrointestinal tract, bacteria, products of bacterial decomposition, unabsorbed digested materials, and indigestible parts of food.

Although 90% of all water absorption occurs in the small intestine, the large intestine absorbs enough to make it an important organ in maintaining the body’s water balance. Of the 0.5–1.0 liter of water that enters the large intestine, all but about 100–200 mL is normally absorbed via osmosis. The large intestine also absorbs ions, including sodium and chloride, and some vitamins.

---

### CLINICAL CONNECTION

**Occult Blood**

The term **occult blood** refers to blood that is hidden; it is not detectable by the human eye. The main diagnostic value of occult blood testing is to screen for colorectal cancer. Two substances often examined for occult blood are feces and urine. Several types of products are available for at-home testing for hidden blood in feces. The tests are based on color changes when reagents are added to feces. The presence of occult blood in urine may be detected at home by using dip-and-read reagent strips.

**The Defecation Reflex**

Mass peristaltic movements push fecal material from the sigmoid colon into the rectum. The resulting distension of the rectal wall stimulates stretch receptors, which initiates a defecation reflex that empties the rectum. The defecation reflex occurs as follows: In response to distension of the rectal wall, the receptors send sensory nerve impulses to the sacral spinal cord. Motor impulses from the cord travel along parasympathetic nerves back to the descending colon, sigmoid colon, rectum, and anus. The resulting contraction of the longitudinal rectal muscles shortens the rectum, thereby increasing the pressure within it. This pressure, along with voluntary contractions of the diaphragm and abdominal muscles, plus parasympathetic stimulation, opens the internal anal sphincter.

The external anal sphincter is voluntarily controlled. If it is voluntarily relaxed, defecation occurs and the feces are expelled through the anus; if it is voluntarily constricted, defecation can be postponed. Voluntary contractions of the diaphragm and abdominal muscles aid defecation by increasing the pressure within the abdomen, which pushes the walls of the sigmoid colon and rectum inward. If defecation does not occur, the feces back up into the sigmoid colon until the next wave of mass peristalsis stimulates the stretch receptors, again creating the urge to defecate. In infants, the defecation reflex causes automatic emptying of the rectum because voluntary control of the external anal sphincter has not yet developed.

The amount of bowel movements that a person has over a given period of time depends on various factors such as diet, health, and stress. The normal range of bowel activity varies from two or three bowel movements per day to three or four bowel movements per week.

**Diarrhea** (di-a-RÉ-a; dia- = through; rhea = flow) is an increase in the frequency, volume, and fluid content of the feces caused by increased motility of and decreased absorption by the intestines. When chyme passes too quickly through the small intestine and feces pass too quickly through the large intestine, there is not enough time for absorption. Frequent diarrhea can result in dehydration and electrolyte imbalances. Excessive motility may be caused by lactose intolerance, stress, and microbes that irritate the gastrointestinal mucosa.

**Constipation** (kon-sti-PÄ-shun; con- = together; stip- = to press) refers to infrequent or difficult defecation caused by decreased motility of the intestines. Because the feces remain in the colon for prolonged periods, excessive water absorption...
A common treatment is a mild laxative, such as milk of magnesia, which induces defecation. However, many physicians maintain that laxatives are habit-forming, and that adding fiber to the diet, increasing the amount of exercise, and increasing fluid intake are safer ways of controlling this common problem.

Table 24.6 summarizes the digestive activities in the large intestine, and Table 24.7 summarizes the functions of all digestive system organs.

</table>
PHASES OF DIGESTION

OBJECTIVES

• Describe the three phases of digestion.
• Describe the major hormones that regulate digestive activities.

Digestive activities occur in three overlapping phases: the cephalic phase, the gastric phase, and the intestinal phase.

Cephalic Phase

During the cephalic phase of digestion, the smell, sight, thought, or initial taste of food activates neural centers in the cerebral cortex, hypothalamus, and brain stem. The brain stem then activates the facial (VII), glossopharyngeal (IX), and vagus (X) nerves. The facial and glossopharyngeal nerves stimulate the salivary glands to secrete saliva, while the vagus nerves stimulate the gastric glands to secrete gastric juice. The purpose of the cephalic phase of digestion is to prepare the mouth and stomach for food that is about to be eaten.

Gastric Phase

Once food reaches the stomach, the gastric phase of digestion begins. Neural and hormonal mechanisms regulate the gastric phase of digestion to promote gastric secretion and gastric motility.

• Neural regulation. Food of any kind distends the stomach and stimulates stretch receptors in its walls. Chemoreceptors in the stomach monitor the pH of the stomach chyme. When the stomach walls are distended or pH increases because proteins have entered the stomach and buffered some of the stomach acid, the stretch receptors and chemoreceptors are activated, and a neural negative feedback loop is set in motion (Figure 24.24). From the stretch receptors and chemoreceptors, nerve impulses propagate to the submucosal plexus, where they activate parasympathetic and enteric neurons. The resulting nerve impulses cause waves of peristalsis and continue to stimulate the flow of gastric juice from gastric glands. The peristaltic waves mix the food with gastric juice; when the waves become strong enough, a small quantity of chyme undergoes gastric emptying into the duodenum. The pH of the stomach chyme decreases (becomes more acidic) and the distension of the stomach walls lessens because chyme has passed into the small intestine, suppressing secretion of gastric juice.

Why does food initially cause the pH of the gastric juice to rise?

Figure 24.24 Neural negative feedback regulation of the pH of gastric juice and gastric motility during the gastric phase of digestion.

Food entering the stomach disrupts homeostasis by

- Increasing pH of gastric juice
- Distention (stretching) of stomach walls

Receptors

Chemo-
receptors and stretch receptors in stomach detect pH increase and distention

Control center

Submucosal plexus

Output

Nerve impulses (parasympathetic)

Effectors

Parietal cells secrete HCl and smooth muscle in stomach wall contracts more vigorously

Increase in acidity of stomach chyme; mixing of stomach contents; emptying of stomach

Return to homeostasis when response brings pH of gastric juice and distention of stomach walls back to normal (pre-eating status)
CHAPTER 24 • THE DIGESTIVE SYSTEM

- **Hormonal regulation.** Gastric secretion during the gastric phase is also regulated by the hormone gastrin. Gastrin is released from the G cells of the gastric glands in response to several stimuli: distension of the stomach by chyme, partially digested proteins in chyme, the high pH of chyme due to the presence of food in the stomach, caffeine in gastric chyme, and acetylcholine released from parasympathetic neurons. Once it is released, gastrin enters the bloodstream, makes a round-trip through the body, and finally reaches its target organs in the digestive system. Gastrin stimulates gastric glands to secrete large amounts of gastric juice. It also strengthens the contraction of the lower esophageal sphincter to prevent reflux of acid chyme into the esophagus, increases motility of the stomach, and relaxes the pyloric sphincter, which promotes gastric emptying. Gastrin secretion is inhibited when the pH of gastric juice drops below 2.0 and is stimulated when the pH rises. This negative feedback mechanism helps provide an optimal low pH for the functioning of pepsin, the killing of microbes, and the denaturing of proteins in the stomach.

**Intestinal Phase**

The intestinal phase of digestion begins once food enters the small intestine. In contrast to reflexes initiated during the cephalic and gastric phases, which stimulate stomach secretory activity and motility, those occurring during the intestinal phase have inhibitory effects that slow the exit of chyme from the stomach. This prevents the duodenum from being overloaded with more chyme than it can handle. In addition, responses occurring during the intestinal phase promote the continued digestion of foods that have reached the small intestine. These activities of the intestinal phase of digestion are regulated by neural and hormonal mechanisms.

- **Neural regulation.** Distension of the duodenum by the presence of chyme causes the enterogastric reflex. Stretch receptors in the duodenal wall send nerve impulses to the medulla oblongata, where they inhibit parasympathetic stimulation and stimulate the sympathetic nerves to the stomach. As a result, gastric motility is inhibited and there is an increase in the contraction of the pyloric sphincter, which decreases gastric emptying.

- **Hormonal regulation.** The intestinal phase of digestion is mediated by two major hormones secreted by the small intestine: cholecystokinin and secretin. **Cholecystokinin (CCK)** is secreted by the CCK cells of the small intestinal crypts of Lieberkühn in response to chyme containing amino acids from partially digested proteins and fatty acids from partially digested triglycerides. CCK stimulates secretion of pancreatic juice that is rich in digestive enzymes. It also causes contraction of the wall of the gallbladder, which squeezes stored bile out of the gallbladder into the cystic duct and through the common bile duct. In addition, CCK causes relaxation of the sphincter of the hepatopancreatic ampulla (sphincter of Oddi), which allows pancreatic juice and bile to flow into the duodenum. CCK also slows gastric emptying by promoting contraction of the pyloric sphincter, produces satiety (a feeling of fullness) by acting on the hypothalamus in the brain, promotes normal growth and maintenance of the pancreas, and enhances the effects of secretin. Acidic chyme entering the duodenum stimulates the release of secretin from the S cells of the small intestinal crypts of Lieberkühn. In turn, secretin stimulates the flow of pancreatic juice that is rich in bicarbonate ($\text{HCO}_3^-$) ions to buffer the acidic chyme that enters the duodenum from the small intestine. Besides this major effect, secretin inhibits secretion of gastric juice, promotes normal growth and maintenance of the pancreas, and enhances the effects of CCK. Overall, secretin causes buffering of acid in chyme that reaches the duodenum and slows production of acid in the stomach.

<td>Cholecystokinin (CCK)</td>
<td>Partially digested proteins (amino acids), triglycerides, and fatty acids that enter the small intestine stimulate secretion of CCK by enteroendocrine CCK cells in the mucosa of the small intestine; CCK is also released in the brain.</td>
<td>Major effects: Stimulates secretion of pancreatic juice rich in digestive enzymes, causes ejection of bile from the gallbladder and opening of the sphincter of the hepatopancreatic ampulla (sphincter of Oddi), and induces satiety (feeling full to satisfaction). Minor effects: Inhibits gastric emptying, promotes normal growth and maintenance of the pancreas, and enhances effects of secretin.</td>

Other Hormones of the Digestive System

Besides gastrin, CCK, and secretin, at least 10 other so-called “gut hormones” are secreted by and have effects on the GI tract. They include motilin, substance P, and bombesin, which stimulate motility of the intestines; vasoactive intestinal polypeptide (VIP), which stimulates secretion of ions and water by the intestines and inhibits gastric acid secretion; gastrin-releasing peptide, which stimulates release of gastrin; and somatostatin, which inhibits gastrin release. Some of these hormones are thought to act as local hormones (paracrines), whereas others are secreted into the blood or even into the lumen of the GI tract. The physiological roles of these and other gut hormones are still under investigation.

Table 24.8 on page 966 summarizes the major hormones that control digestion.

CHECKPOINT

44. What is the purpose of the cephalic phase of digestion?
45. Describe the role of gastrin in the gastric phase of digestion.
46. Outline the steps of the enterogastric reflex.
47. Explain the roles of CCK and secretin in the intestinal phase of digestion.

DEVELOPMENT OF THE DIGESTIVE SYSTEM

OBJECTIVE

• Describe the development of the digestive system.

During the fourth week of development, the cells of the endoderm form a cavity called the primitive gut, the forerunner of the gastrointestinal tract (see Figure 29.12b on page 1148). Soon afterwards the mesoderm forms and splits into two layers (somatic and splanchnic), as shown in Figure 29.9d on page 1143. The splanchnic mesoderm associates with the endoderm of the primitive gut; as a result, the primitive gut has a double-layered wall. The endodermal layer gives rise to the epithelial lining and glands of most of the gastrointestinal tract; the mesodermal layer produces the smooth muscle and connective tissue of the tract.

The primitive gut elongates and differentiates into an anterior foregut, an intermediate midgut, and a posterior hindgut (see Figure 29.12c). Until the fifth week of development, the midgut opens into the yolk sac; after that time, the yolk sac constricts and detaches from the midgut, and the midgut seals. In the region of the foregut, a depression consisting of ectoderm, the stomodeum (stō-mō-DÉ-um), appears (see Figure 29.12d), which develops into the oral cavity. The oropharyngeal membrane is a depression of fused ectoderm and endoderm on the surface of the embryo that separates the foregut from the stomodeum. The membrane ruptures during the fourth week of development, so that the foregut is continuous with the outside of the embryo through the oral cavity. Another depression consisting of ectoderm, the proctodeum (prok-tō-DÉ-um), forms in the hindgut and goes on to develop into the anus (see Figure 29.12d). The cloacal membrane (klō-Ă-kul) is a fused membrane of ectoderm and endoderm that separates the hindgut from the proctodeum. After it ruptures during the seventh week, the hindgut is continuous with the outside of the embryo through the anus. Thus, the gastrointestinal tract forms a continuous tube from mouth to anus.

The foregut develops into the pharynx, esophagus, stomach, and part of the duodenum. The midgut is transformed into the remainder of the duodenum, the jejunum, the ileum, and portions of the large intestine (cecum, appendix, ascending colon, and most of the transverse colon). The hindgut develops into the remainder of the large intestine, except for a portion of the anal canal that is derived from the proctodeum.

As development progresses, the endoderm at various places along the foregut develops into hollow buds that grow into the mesoderm. These buds will develop into the salivary glands, liver, gallbladder, and pancreas. Each of these organs retains a connection with the gastrointestinal tract through ducts.

CHECKPOINT

48. What structures develop from the foregut, midgut, and hindgut?

AGING AND THE DIGESTIVE SYSTEM

OBJECTIVE

• Describe the effects of aging on the digestive system.

Overall changes of the digestive system associated with aging include decreased secretory mechanisms, decreased motility of the digestive organs, loss of strength and tone of the muscular tissue and its supporting structures, changes in neurosensory feedback regarding enzyme and hormone release, and diminished response to pain and internal sensations. In the upper portion of the GI tract, common changes include reduced sensitivity to mouth irritations and sores, loss of taste, periodontal disease, difficulty in swallowing, hiatal hernia, gastritis, and peptic ulcer disease. Changes that may appear in the small intestine include duodenal ulcers, malabsorption, and maldigestion. Other pathologies that increase in incidence with age are appendicitis, gallbladder problems, jaundice, cirrhosis, and acute pancreatitis. Large intestinal changes such as constipation, hemorrhoids, and diverticular disease may also occur. Cancer of the colon or rectum is quite common, as are bowel obstructions and impactions.

CHECKPOINT

49. What are the general effects of aging on the digestive system?

Now that our exploration of the digestive system is complete, you can appreciate the many ways that this system contributes to homeostasis of other body systems by examining Focus on Homeostasis: The Digestive System. Next, in Chapter 25, you will discover how the nutrients absorbed by the GI tract enter into metabolic reactions in the body tissues.
Focus on Homeostasis

For all body systems:

The digestive system breaks down dietary nutrients into forms that can be absorbed and used by body cells for producing ATP and building body tissues. Absorbs water, minerals, and vitamins needed for growth and function of body tissues; and eliminates wastes from body tissues in feces.

Integumentary system:

Small intestine absorbs vitamin D, which skin and kidneys modify to produce the hormone calcitriol. Excess dietary calories are stored as triglycerides in adipose cells in dermis and subcutaneous layer.

Skeletal system:

Small intestine absorbs dietary calcium and phosphorus salts needed to build bone extracellular matrix.

Muscular system:

Liver can convert lactic acid (produced by muscles during exercise) to glucose.

Nervous system:

Gluconeogenesis (synthesis of new glucose molecules) in liver plus digestion and absorption of dietary carbohydrates provide glucose, needed for ATP production by neurons.

Endocrine system:

Liver inactivates some hormones, ending their activity. Pancreatic islets release insulin and glucagon. Cells in mucosa of stomach and small intestine release hormones that regulate digestive activities. Liver produces angiotensinogen.

Cardiovascular system:

GI tract absorbs water that helps maintain blood volume and iron that is needed for synthesis of hemoglobin in red blood cells. Bilirubin from hemoglobin breakdown is partially excreted in feces. Liver synthesizes most plasma proteins.

Lymphatic system and immunity:

Acidity of gastric juice destroys bacteria and most toxins in stomach.

Respiratory system:

Pressure of abdominal organs against the diaphragm helps expel air quickly during a forced exhalation.

Urinary system:

Absorption of water by GI tract provides water needed to excrete waste products in urine.

Reproductive systems:

Digestion and absorption provides adequate nutrients, including fats, for normal development of reproductive structures, for production of gametes (oocytes and sperm), and for fetal growth and development during pregnancy.
Dental Caries

Dental caries, or tooth decay, involves a gradual demineralization (softening) of the enamel and dentin. If untreated, microorganisms may invade the pulp, causing inflammation and infection, with subsequent death of the pulp and abscess of the alveolar bone surrounding the root’s apex, requiring root canal therapy (see page 932).

Dental caries begin when bacteria, acting on sugars, produce acids that demineralize the enamel. Dextran, a sticky polysaccharide produced from sucrose, causes the bacteria to stick to the teeth. Masses of bacterial cells, dextran, and other debris adhering to teeth constitute dental plaque. Saliva cannot reach the tooth surface to buffer the acid because the plaque covers the teeth. Brushing the teeth after eating removes the plaque from flat surfaces before the bacteria can produce acids. Dentists also recommend that the plaque between the teeth be removed every 24 hours with dental floss.

Periodontal Disease

Periodontal disease is a collective term for a variety of conditions characterized by inflammation and degeneration of the gingivae, alveolar bone, periodontal ligament, and cementum. In one such condition, called pyorrhea, initial symptoms include enlargement and inflammation of the soft tissue and bleeding of the gums. Without treatment, the soft tissue may deteriorate and the alveolar bone may be resorbed, causing loosening of the teeth and recession of the gums. Periodontal diseases are often caused by poor oral hygiene; by local irritants, such as bacteria, impacted food, and cigarette smoke; or by a poor “bite.”

Peptic Ulcer Disease

In the United States, 5–10% of the population develops peptic ulcer disease (PUD). An ulcer is a craterlike lesion in a membrane; ulcers that develop in areas of the GI tract exposed to acidic gastric juice are called peptic ulcers. The most common complication of peptic ulcers is bleeding, which can lead to anemia if enough blood is lost. In acute cases, peptic ulcers can lead to shock and death. Three distinct causes of PUD are recognized: (1) the bacterium Helicobacter pylori; (2) nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin; and (3) hypersecretion of HCl, as occurs in Zollinger-Ellison syndrome, a gastrin-producing tumor, usually of the pancreas.

Helicobacter pylori (previously named Campylobacter pylori) is the most frequent cause of PUD. The bacterium produces an enzyme called urease, which splits urea into ammonia and carbon dioxide. While shielding the bacterium from the acidity of the stomach, the ammonia also damages the protective mucous layer of the stomach and the underlying gastric cells. H. pylori also produces catalase, an enzyme that may protect the microbe from phagocytosis by neutrophils, plus several adhesion proteins that allow the bacterium to attach itself to gastric cells.

Several therapeutic approaches are helpful in the treatment of PUD. Cigarette smoke, alcohol, caffeine, and NSAIDs should be avoided because they can impair mucosal defensive mechanisms, which increases mucosal susceptibility to the damaging effects of HCl. In cases associated with H. pylori, treatment with an antibiotic drug often resolves the problem. Oral antacids such as Tums® or Maalox®, can help temporarily by buffering gastric acid. When hypersecretion of HCl is the cause of PUD, H2 blockers (such as Tagamet®) or proton pump inhibitors such as omeprazole (Prilosec®), which block secretion of H+ from parietal cells, may be used.

Dental caries begin when bacteria, acting on sugars, produce acids that demineralize the enamel. Dextran, a sticky polysaccharide produced from sucrose, causes the bacteria to stick to the teeth. Masses of bacterial cells, dextran, and other debris adhering to teeth constitute dental plaque. Saliva cannot reach the tooth surface to buffer the acid because the plaque covers the teeth. Brushing the teeth after eating removes the plaque from flat surfaces before the bacteria can produce acids. Dentists also recommend that the plaque between the teeth be removed every 24 hours with dental floss.

Diverticular Disease

In diverticular disease, saclike outpouchings of the wall of the colon, termed diverticula, occur in places where the muscularis has weakened and may become inflamed. Development of diverticula is known as diverticulosis. Many people who develop diverticulosis have no symptoms and experience no complications. Of those people known to have diverticulosis, 10–25% eventually develop an inflammation known as diverticulitis. This condition may be characterized by pain, either constipation or increased frequency of defecation, nausea, vomiting, and low-grade fever. Because diets low in fiber contribute to development of diverticulitis, patients who change to high-fiber diets show marked relief of symptoms. In severe cases, affected portions of the colon may require surgical removal. If diverticula rupture, the release of bacteria into the abdominal cavity can cause peritonitis.

Colorectal Cancer

Colorectal cancer is among the deadliest of malignancies, ranking second to lung cancer in males and third after lung cancer and breast cancer in females. Genetics plays a very important role; an inherited predisposition contributes to more than half of all cases of colorectal cancer. Intake of alcohol and diets high in animal fat and protein are associated with increased risk of colorectal cancer; dietary fiber, retinoids, calcium, and selenium may be protective. Signs and symptoms of colorectal cancer include diarrhea, constipation, cramping, abdominal pain, and rectal bleeding, either visible or occult (hidden in feces). Precancerous growths on the mucosal surface, called polyps, also increase the risk of developing colorectal cancer. Screening for colorectal cancer includes testing for blood in the feces, digital rectal examination, sigmoidoscopy, colonoscopy, and barium enema. Tumors may be removed endoscopically or surgically.

Hepatitis

Hepatitis is an inflammation of the liver that can be caused by viruses, drugs, and chemicals, including alcohol. Clinically, several types of viral hepatitis are recognized.

Hepatitis A (infectious hepatitis) is caused by the hepatitis A virus and is spread via fecal contamination of objects such as food, clothing, toys, and eating utensils (fecal–oral route). It is generally a mild disease of children and young adults characterized by loss of appetite, malaise, nausea, diarrhea, fever, and chills. Eventually, jaundice appears. This type of hepatitis does not cause lasting liver damage. Most people recover in 4 to 6 weeks.

Hepatitis B is caused by the hepatitis B virus and is spread primarily by sexual contact and contaminated syringes and transfusion equipment. It can also be spread via saliva and tears. Hepatitis B virus can be present for years or even a lifetime, and it can produce cirrhosis and possibly cancer of the liver. Individuals who harbor the active hepatitis B virus also become carriers. Vaccines produced through recombinant DNA technology (for example, Recombivax HB®) are available to prevent hepatitis B infection.

Hepatitis C, caused by the hepatitis C virus, is clinically similar to hepatitis B. Hepatitis C can cause cirrhosis and possibly liver cancer. In developed nations, donated blood is screened for the presence of hepatitis B and C.

Hepatitis D is caused by the hepatitis D virus. It is transmitted like hepatitis B and in fact a person must have been co-infected with hepatitis D before contracting hepatitis D. Hepatitis D results in severe
CHAPTER 24

Anorexia nervosa

Anorexia nervosa have a fixation on weight control and often insist on having changes that result from nutritional depletion. Patients with anorexia nervosa have a high mortality rate among pregnant women.

MEDICAL TERMINOLOGY

*Achalasia* (ak-*a-LA-zē-a; *a* - without; *chalasis* = relaxation) A condition caused by malfunction of the myenteric plexus in which the lower esophageal sphincter fails to relax normally as food approaches. A whole meal may become lodged in the esophagus and enter the stomach very slowly. Distension of the esophageal results in chest pain that is often confused with pain originating from the heart.

*Borborygmus* (bor-*bō-RIG-mus) A rumbling noise caused by the propulsion of gas through the intestines.

*Bulimia* (bu-* = ox; *limia* = hunger) or binge–purge syndrome A disorder that typically affects young, single, middle-class, white females, characterized by overeating at least twice a week followed by purging by self-induced vomiting, strict dieting or fasting, vigorous exercise, or use of laxatives or diuretics; it occurs in response to fears of being overweight or to stress, depression, and physiological disorders such as hypothalamic tumors.

*Canker sore* (KANG-ker) Painful ulcer on the mucous membrane of the mouth that affects females more often than males, usually between ages 10 and 40; may be an autoimmune reaction or a food allergy.

*Cirrhosis* Distorted or scarred liver as a result of chronic inflammation due to hepatitis, chemicals that destroy hepatocytes, parasites that infect the liver, or alcoholism; the hepatocytes are replaced by fibrous or adipose connective tissue. Symptoms include jaundice, edema in the legs, uncontrolled bleeding, and increased sensitivity to drugs.

*Colitis* (ko-LI-tis) Inflammation of the mucosa of the colon and rectum in which absorption of water and salts is reduced, producing watery, bloody feces and, in severe cases, dehydration and salt depletion. Spasms of the irritated muscularis produce cramps. It is thought to be an autoimmune condition.

*Colonoscopy* (kō-ôn-OS-kō-pē; -skopes = to view) The visual examination of the lining of the colon using an elongated, flexible, fiberoptic endoscope called a colonoscope. It is used to detect disorders such as polyps, cancer, and diverticulosis, to take tissue samples, and to remove small polyps. Most tumors of the large intestine occur in the rectum.

*Colostomy* (kō-ÔS tô-mē; -stomy = provide an opening) The diversion of feces through an opening in the colon, creating a surgical “stoma” (artificial opening) that is made in the exterior of the abdominal wall. This opening serves as a substitute anus through which feces are eliminated into a bag worn on the abdomen.

*Dysphagia* (dis-FĀ-jē-ə; *dys* = abnormal; *phagia* = to eat) Difficulty in swallowing that may be caused by inflammation, paralysis, obstruction, or trauma.

*Flatus* (FLĀ-tus) Air (gas) in the stomach or intestine, usually expelled through the anus. If the gas is expelled through the mouth, it is called eructation or belching (burping). Flatus may result from gas released during the breakdown of foods in the stomach or from swallowing air or gas-containing substances such as carbonated drinks.

*Food poisoning* A sudden illness caused by ingesting food or drink contaminated by an infectious microbe (bacterium, virus, or protozoan) or a toxin (poison). The most common cause of food poisoning is the toxin produced by the bacterium *Staphylococcus aureus*. Most types of food poisoning cause diarrhea and/or vomiting, often associated with abdominal pain.

*Gastroenteritis* (gas-*t∗-en-ter-i-tis; *gastro-* = stomach; *enteron* = intestine; -*itis* = inflammation) Inflammation of the lining of the stomach and intestine (especially the small intestine). It is usually caused by a viral or bacterial infection that may be acquired by contaminated food or water or by people in close contact. Symptoms include diarrhea, vomiting, fever, loss of appetite, cramps, and abdominal discomfort.

*Gastroscopy* (gas-TROS-kō-pē; -scopy = to view with a lighted instrument) Endoscopic examination of the stomach in which the examiner can view the interior of the stomach directly to evaluate an ulcer, tumor, inflammation, or source of bleeding.

*Halitosis* (hal-*i-TÔ-sis; halitus- = breath; -*osis* = condition) A foul odor from the mouth; also called bad breath.

*Heartburn* A burning sensation in a region near the heart due to irritation of the mucosa of the esophagus from hydrochloric acid in stomach contents. It is caused by failure of the lower esophageal sphincter to close properly, so that the stomach contents enter the inferior esophagus. It is not related to any cardiac problem.

*Hemorrhoids* (HEM-ô-royds; *hēmi* = blood; *rhaia* = flow) Varicose (enlarged and inflamed) superior rectal veins. Hemorrhoids develop when the veins are put under pressure and become engorged with blood. If the pressure continues, the wall of the vein stretches. Such a distended vessel oozes blood; bleeding or itching is usually the first sign that a hemorrhoid has developed. Stretching of a vein also favors clot formation, further aggravating swelling and pain. Hemorrhoids may be caused by constipation, which may be brought on by low-fiber diets. Also, repeated straining during defecation forces blood down into the rectal veins, increasing pressure in those veins and possibly causing hemorrhoids. Also called piles.
Hernia (HER-nē-a) Protrusion of all or part of an organ through a membrane or cavity wall, usually the abdominal cavity. Hiatus (diaphragmatic) hernia is the protrusion of a part of the stomach into the thoracic cavity through the esophageal hiatus of the diaphragm. Inguinal hernia is the protrusion of the hernial sac into the inguinal opening; it may contain a portion of the bowel in an advanced stage and may extend into the scrotal compartment in males, causing strangulation of the herniated part.

Inflammatory bowel disease (in-FLAM-a-tō'-re BOW-el) Inflammation of the gastrointestinal tract that exists in two forms. (1) Crohn’s disease is an inflammation of any part of the gastrointestinal tract in which the inflammation extends from the mucosa through the submucosa, muscularis, and serosa. (2) Ulcerative colitis is an inflammation of the mucosa of the colon and rectum, usually accompanied by rectal bleeding. Curiously, cigarette smoking increases the risk of Crohn’s disease but decreases the risk of ulcerative colitis.

Irritable bowel syndrome (IBS) Disease of the entire gastrointestinal tract in which a person reacts to stress by developing symptoms (such as cramping and abdominal pain) associated with alternating patterns of diarrhea and constipation. Excessive amounts of mucus may appear in feces; other symptoms include flatulence, nausea, and loss of appetite. The condition is also known as irritable colon or spastic colitis.

Hernia (HER-nē-a) Protrusion of all or part of an organ through a membrane or cavity wall, usually the abdominal cavity. Hiatus (diaphragmatic) hernia is the protrusion of a part of the stomach into the thoracic cavity through the esophageal hiatus of the diaphragm. Inguinal hernia is the protrusion of the hernial sac into the inguinal opening; it may contain a portion of the bowel in an advanced stage and may extend into the scrotal compartment in males, causing strangulation of the herniated part.

Inflammatory bowel disease (in-FLAM-a-tō'-re BOW-el) Inflammation of the gastrointestinal tract that exists in two forms. (1) Crohn’s disease is an inflammation of any part of the gastrointestinal tract in which the inflammation extends from the mucosa through the submucosa, muscularis, and serosa. (2) Ulcerative colitis is an inflammation of the mucosa of the colon and rectum, usually accompanied by rectal bleeding. Curiously, cigarette smoking increases the risk of Crohn’s disease but decreases the risk of ulcerative colitis.

Irritable bowel syndrome (IBS) Disease of the entire gastrointestinal tract in which a person reacts to stress by developing symptoms (such as cramping and abdominal pain) associated with alternating patterns of diarrhea and constipation. Excessive amounts of mucus may appear in feces; other symptoms include flatulence, nausea, and loss of appetite. The condition is also known as irritable colon or spastic colitis.

Malabsorption (mal-ab-SORP-shun; mal- = bad) A number of disorders in which nutrients from food are not absorbed properly. It may be due to disorders that result in the inadequate breakdown of food during digestion (due to inadequate digestive enzymes or juices), damage to the lining of the small intestine (from surgery, infections, and drugs like neomycin and alcohol), and impairment of motility. Symptoms may include diarrhea, weight loss, weakness, vitamin deficiencies, and bone demineralization.

Malocclusion (mal’-ō-KLOO-zhen; mal- = bad; occlusion = to fit together) Condition in which the surfaces of the maxillary (upper) and mandibular (lower) teeth fit together poorly.

Nausea (NAW-se-a; nausía = seasickness) Discomfort characterized by a loss of appetite and the sensation of impending vomiting. Its causes include local irritation of the gastrointestinal tract, a systemic disease, brain disease or injury, overexertion, or the effects of medication or drug overdosage.

Traveler’s diarrhea Infectious disease of the gastrointestinal tract that results in loose, urgent bowel movements, cramping, abdominal pain, malaise, nausea, and occasionally fever and dehydration. It is acquired through ingestion of food or water contaminated with fecal material typically containing bacteria (especially Escherichia coli); viruses or protozoan parasites are less common causes.

Hernia (HER-nē-a) Protrusion of all or part of an organ through a membrane or cavity wall, usually the abdominal cavity. Hiatus (diaphragmatic) hernia is the protrusion of a part of the stomach into the thoracic cavity through the esophageal hiatus of the diaphragm. Inguinal hernia is the protrusion of the hernial sac into the inguinal opening; it may contain a portion of the bowel in an advanced stage and may extend into the scrotal compartment in males, causing strangulation of the herniated part.

972 CHAPTER 24 • THE DIGESTIVE SYSTEM

Mouth (p. 928)
1. The mouth is formed by the cheeks, hard and soft palates, lips, and tongue.
2. The vestibule is the space bounded externally by the cheeks and lips and internally by the teeth and gums.
3. The oral cavity proper extends from the vestibule to the fauces.
4. The tongue, together with its associated muscles, forms the floor of the oral cavity. It is composed of skeletal muscle covered with mucous membrane.
5. The upper surface and sides of the tongue are covered with papillae, some of which contain taste buds.
6. The major portion of saliva is secreted by the major salivary glands, which lie outside the mouth and pour their contents into ducts that empty into the oral cavity.
7. There are three pairs of major salivary glands: parotid, submandibular, and sublingual glands.
8. Saliva lubricates food and starts the chemical digestion of carbohydrates.
9. Salivation is controlled by the nervous system.
10. The teeth (dentes) project into the mouth and are adapted for mechanical digestion.
11. A typical tooth consists of three principal regions: crown, root, and neck.
12. Teeth are composed primarily of dentin and are covered by enamel, the hardest substance in the body.
13. There are two dentitions: deciduous and permanent.
14. Through mastication, food is mixed with saliva and shaped into a soft, flexible mass called a bolus.
15. Salivary amylase begins the digestion of starches, and lingual lipase acts on triglycerides.

Pharynx (p. 934)
1. The pharynx is a funnel-shaped tube that extends from the internal nares to the esophagus posteriorly and to the larynx anteriorly.
2. The pharynx has both respiratory and digestive functions.

Esophagus (p. 934)
1. The esophagus is a collapsible, muscular tube that connects the pharynx to the stomach.
2. It contains an upper and a lower esophageal sphincter.

Deglutition (p. 935)
1. Deglutition, or swallowing, moves a bolus from the mouth to the stomach.
2. Swallowing consists of a voluntary stage, a pharyngeal stage (involuntary), and an esophageal stage (involuntary).

Stomach (p. 937)
1. The stomach connects the esophagus to the duodenum.
2. The principal anatomic regions of the stomach are the cardia, fundus, body, and pylorus.
3. Adaptations of the stomach for digestion include rugae; glands that produce mucus, hydrochloric acid, pepsin, gastric lipase, and intrinsic factor; and a three-layered muscularis.
4. Mechanical digestion consists of mixing waves.
5. Chemical digestion consists mostly of the conversion of proteins into peptides by pepsin.
6. The stomach wall is impermeable to most substances.
7. Among the substances the stomach can absorb are water, certain ions, drugs, and alcohol.

Pancreas (p. 942)
1. The pancreas consists of a head, a body, and a tail and is connected to the duodenum via the pancreatic duct and accessory duct.
2. Endocrine pancreatic islets (islets of Langerhans) secrete hormones, and exocrine acini secrete pancreatic juice.
3. Pancreatic juice contains enzymes that digest starch (pancreatic amylase), proteins (trypsin, chymotrypsin, carboxypeptidase, and elastase), triglycerides (pancreatic lipase), and nucleic acids (ribonuclease and deoxyribonuclease).

Liver and Gallbladder (p. 945)
1. The liver has left and right lobes; the right lobe includes a quadrate lobe and a caudate lobe. The gallbladder is a sac located in a depression on the posterior surface of the liver that stores and concentrates bile.
2. The lobes of the liver are made up of lobules that contain hepatocytes (liver cells), sinusoids, stellate reticuloendothelial (Kupffer) cells, and a central vein.
3. Hepatocytes produce bile that is carried by a duct system to the gallbladder for concentration and temporary storage.
4. Bile’s contribution to digestion is the emulsification of dietary lipids.
5. The liver also functions in carbohydrate, lipid, and protein metabolism; processing of drugs and hormones; excretion of bilirubin; synthesis of bile salts; storage of vitamins and minerals; phagocytosis, and activation of vitamin D.

Small Intestine (p. 949)
1. The small intestine extends from the pyloric sphincter to the ileocecal sphincter.
2. It is divided into duodenum, jejunum, and ileum.
3. Its glands secrete fluid and mucus, and the circular folds, villi, and microvilli of its wall provide a large surface area for digestion and absorption.
4. Brush-border enzymes digest α-dextrins, maltose, sucrose, lactose, peptides, and nucleotides at the surface of mucosal epithelial cells.
5. Pancreatic and intestinal brush-border enzymes break down starches into maltose, maltooliase, and α-dextrins (pancreatic amylase), α-dextrins into glucose (α-dextrinase), maltose to glucose (maltase), sucrose to glucose and fructose (sucrase), lactose to glucose and galactose (lactase), and proteins into peptides (trypsin, chymotrypsin, and elastase). Also, enzymes break off amino acids at the carboxyl ends of peptides (carboxypeptidases) and break off amino acids at the amino ends of peptides (aminopeptidases). Finally, enzymes split dipeptides into amino acids (dipeptidases), trypglycerides to fatty acids and monoglycerides (lipases), and nucleotides to pentoses and nitrogenous bases (nucleosidases and phosphatases).
6. Mechanical digestion in the small intestine involves segmentation and migrating motility complexes.
7. Absorption occurs via diffusion, facilitated diffusion, osmosis, and active transport; most absorption occurs in the small intestine.
8. Monosaccharides, amino acids, and short-chain fatty acids pass into the blood capillaries.
Large Intestine (p. 959)
1. The large intestine extends from the ileocecal sphincter to the anus.
2. Its regions include the cecum, colon, rectum, and anal canal.
3. The mucosa contains many goblet cells, and the muscularis consists of teniae coli and haustra.
4. Mechanical movements of the large intestine include haustral churning, peristalsis, and mass peristalsis.
5. The last stages of chemical digestion occur in the large intestine through bacterial action. Substances are further broken down, and some vitamins are synthesized.
6. The large intestine absorbs water, ions, and vitamins.
7. Feces consist of water, inorganic salts, epithelial cells, bacteria, and undigested foods.
8. The elimination of feces from the rectum is called defecation.
9. Defecation is a reflex action aided by voluntary contractions of the anal sphincter.

Phases of Digestion (p. 965)
1. Digestive activities occur in three overlapping phases: cephalic phase, gastric phase, and intestinal phase.
2. During the cephalic phase of digestion, salivary glands secrete saliva and gastric glands secrete gastric juice in order to prepare the mouth and stomach for food that is about to be eaten.
3. The presence of food in the stomach causes the gastric phase of digestion, which promotes gastric juice secretion and gastric motility.
4. During the intestinal phase of digestion, food is digested in the small intestine. In addition, gastric motility and gastric secretion decrease in order to slow the exit of chyme from the stomach, which prevents the small intestine from being overloaded with more chyme than it can handle.
5. The activities that occur during the various phases of digestion are coordinated by neural pathways and by hormones. Table 24.8 on page 966 summarizes the major hormones that control digestion.

Development of the Digestive System (p. 967)
1. The endoderm of the primitive gut forms the epithelium and glands of most of the gastrointestinal tract.
2. The mesoderm of the primitive gut forms the smooth muscle and connective tissue of the gastrointestinal tract.

Aging and the Digestive System (p. 967)
1. General changes include decreased secretory mechanisms, decreased motility, and loss of tone.
2. Specific changes may include loss of taste, pyorrhea, hernias, peptic ulcer disease, constipation, hemorrhoids, and diverticular diseases.

SELF-QUIZ QUESTIONS
Fill in the blanks in the following statements.
1. The end products of chemical digestion of carbohydrates are _____, of proteins are _____, of lipids are _____ and ____, and of nucleic acids are _____, _____, and ______.
2. List the mechanisms of absorption of materials in the small intestine: ______, ______, ______, and ______.

Indicate whether the following statements are true or false.
3. The soft palate, uvula, and epiglottis prevent swallowed foods and liquids from entering the respiratory passages.
4. The coordinated contractions and relaxations of the muscularis, which propels materials through the GI tract, is known as peristalsis.

Choose the one best answer to the following questions.
5. Which of the following are mismatched?
   (a) chemical digestion: splitting food molecules into simple substances by hydrolysis with the assistance of digestive enzymes
   (b) motility: mechanical processes that break apart ingested food into small molecules
   (c) ingestion: taking foods and liquids into the mouth
   (d) propulsion: movement of food through GI tract due to smooth muscle contraction
   (e) absorption: passage into blood or lymph of ions, fluids and small molecules via the epithelial lining of the GI tract lumen
   (f) assimilation: __________
6. Which of the following are true concerning the peritoneum?
   (1) The kidneys and pancreas are retroperitoneal. (2) The greater omentum is the largest of the peritoneal folds. (3) The lesser omentum binds the large intestine to the posterior abdominal wall. (4) The falciform ligament attaches the liver to the anterior abdominal wall and diaphragm. (5) The mesentery is associated with the jejunum and ileum.
   (a) 1, 2, 3, and 5 (b) 1, 2, 3, and 6 (c) 2 and 5
   (d) 1, 2, 3, and 5 (e) 3, 4, and 5
7. When a surgeon makes an incision in the small intestine, in what order would the physician encounter these structures? (1) epithelium, (2) submucosa, (3) serosa, (4) muscularis, (5) lamina propria, (6) muscularis mucosae.
   (a) 3, 4, 5, 6, 2, 1 (b) 1, 2, 3, 4, 6, 5 (c) 1, 5, 6, 2, 4, 3
   (d) 5, 1, 2, 6, 4, 3 (e) 3, 4, 2, 6, 5, 1
8. Which of the following are functions of the liver? (1) carbohydrate, lipid, and protein metabolism, (2) nucleic acid metabolism, (3) excretion of bilirubin, (4) synthesis of bile salts, (5) activation of vitamin D.
   (a) 1, 2, 3, and 5 (b) 1, 2, 3, and 4 (c) 1, 3, 4, and 5
   (d) 2, 3, 4, and 5 (e) 1, 2, 4, and 5
9. Which of the following statements regarding the regulation of gastric secretion and motility are true? (1) The sight, smell, taste, or thought of food can initiate the cephalic phase of gastric activity. (2) The gastric phase begins when food enters the small intestine. (3) Once activated, stretch receptors and chemoreceptors in the stomach trigger the flow of gastric juice and peristalsis. (4) The intestinal phase reflexes inhibit gastric activity. (5) The enterogastric reflex stimulates gastric emptying.
(a) 1, 3, and 4 (b) 2, 4, and 5 (c) 1, 3, 4, and 5 (d) 1, 2, and 5 (e) 1, 2, 3, and 4

10. Which of the following are true? (1) Segmentations in the small intestine help propel chyme through the intestinal tract. (2) The migrating motility complex is a type of peristalsis in the small intestine. (3) The large surface area for absorption in the small intestine is due to the presence of circular folds, villi, and microvilli. (4) The mucus-producing cells of the small intestine are paneth cells. (5) Most long-chain fatty acid and monoglyceride absorption in the small intestine requires the presence of bile salts.
(a) 1, 2, and 3 (b) 2, 3, and 5 (c) 1, 2, 3, 4, and 5 (d) 1, 3, and 5 (e) 1, 2, 3, and 5

11. The release of feces from the large intestine is dependent on (1) stretching of the rectal walls, (2) voluntary relaxation of the external anal sphincter, (3) involuntary contraction of the diaphragm and abdominal muscles, (4) activity of the intestinal bacteria, (5) sympathetic stimulation of the internal sphincter.
(a) 2, 4, and 5 (b) 1, 2, and 5 (c) 1, 2, 3, and 5 (d) 1 and 2 (e) 3, 4, and 5

12. Which of the following is not true concerning the liver?
(a) The left hepatic duct joins the cystic duct from the gallbladder. (b) As blood passes through the sinusoids, it is processed by hepatocytes and phagocytes. (c) Processed blood returns from the liver to systemic circulation through the hepatic vein. (d) The liver receives oxygenated blood through the hepatic artery. (e) The hepatic portal vein delivers deoxygenated blood from the GI tract to the liver.

13. Match the following:

<table>
<thead>
<tr>
<th>(a) collapsed, muscular tube involved in deglutition and peristalsis</th>
<th>(1) mouth</th>
</tr>
</thead>
<tbody>
<tr>
<td>(b) coiled tube attached to the cecum</td>
<td>(2) teeth</td>
</tr>
<tr>
<td>(c) contains duodenal glands in the submucosa</td>
<td>(3) salivary glands</td>
</tr>
<tr>
<td>(d) produces and secretes bile</td>
<td>(4) pharynx</td>
</tr>
<tr>
<td>(e) contains aggregated lymphatic follicles in the submucosa</td>
<td>(5) esophagus</td>
</tr>
<tr>
<td>(f) responsible for ingestion, mastication, and deglutition</td>
<td>(6) tongue</td>
</tr>
<tr>
<td>(g) responsible for churning, peristalsis, storage, and chemical digestion with the enzyme pepsin</td>
<td>(7) stomach</td>
</tr>
<tr>
<td>(h) storage area for bile</td>
<td>(8) duodenum</td>
</tr>
<tr>
<td>(i) contain acini that release juices containing several digestive enzymes for protein, carbohydrate, lipid, and nucleic acid digestion and sodium bicarbonate to buffer stomach acid</td>
<td>(9) ileum</td>
</tr>
<tr>
<td>(j) composed of enamel, dentin, and pulp cavity; used in mastication</td>
<td>(10) colon</td>
</tr>
<tr>
<td>(k) passageway for food, fluid, and air; involved in deglutition</td>
<td>(11) liver</td>
</tr>
<tr>
<td>(l) forms a semisolid waste material through haustral churning and peristalsis</td>
<td>(12) gallbladder</td>
</tr>
<tr>
<td>(m) forces the food to the back of the mouth for swallowing; places food in contact with the teeth</td>
<td>(13) appendix</td>
</tr>
<tr>
<td>(n) produce a fluid in the mouth that helps cleanse the mouth and teeth and that lubricates, dissolves, and begins the chemical breakdown of food</td>
<td>(14) pancreas</td>
</tr>
</tbody>
</table>
14. Match the following:

(a) an activating brush-border enzyme that splits off part of the trypsinogen molecule to form trypsin, a protease
(b) an enzyme that initiates carbohydrate digestion in the mouth
(c) the principal triglyceride-digesting enzyme in adults
(d) stimulates secretion of gastric juices and promotes gastric emptying
(e) secreted by chief cells in the stomach; a proteolytic enzyme
(f) stimulates the flow of pancreatic juice rich in bicarbonates; decreases gastric secretions
(g) a nonenzymatic fat-emulsifying agent
(h) causes contraction of the gallbladder and stimulates the production of pancreatic juice rich in digestive enzymes
(i) inhibits gastrin release
(j) stimulates secretion of ions and water by the intestines and inhibits gastric acid secretion
(k) secreted by glands in the tongue; begins breakdown of triglycerides in the stomach

15. Match the following:

(a) microvilli of the small intestine that increase surface area for absorption; also contain some digestive enzymes
(b) fingerlike projections of the mucosa of the small intestine that increase surface area for digestion and absorption
(c) produce hydrochloric acid and intrinsic factor in the stomach
(d) secrete lysozyme; help regulate microbial population in the intestines
(e) stomach enteroendocrine cells that secrete gastrin
(f) longitudinal muscular bands in the large intestine; tonic contractions produce haustra
(g) lymphatic capillary used for chylomicron absorption in the small intestine
(h) groups of lymphatic nodules in the small intestine
(i) controls the GI tract motility and secretions of GI tract organs
(j) large mucosal folds in the stomach
(k) secrete pepsinogen and gastric lipase in the stomach
(l) permanent ridges in the mucosa of the small intestine; enhance absorption by increasing surface area and causing chyme to spiral rather than move in a straight line
(m) phagocytic cells of the liver; destroy worn-out white blood cells and red blood cells, bacteria, and other foreign matter in the blood draining the GI tract

CRITICAL THINKING QUESTIONS

1. Why would you not want to completely suppress HCl secretion in the stomach?

2. Trey has cystic fibrosis, a genetic disorder that is characterized by the production of excessive mucus, affecting several body systems (e.g., respiratory, digestive, reproductive). In the digestive system, the excess mucus blocks bile ducts in the liver and pancreatic ducts. How would this affect Trey’s digestive processes?

3. Antonio had dinner at his favorite Italian restaurant. His menu consisted of a salad, a large plate of spaghetti, garlic bread, and wine. For dessert, he consumed “death by chocolate” cake and a cup of coffee. He topped off his evening with a cigarette and brandy. He returned home and, while lying on his couch watching television, he experienced a pain in his chest. He called 911 because he was certain he was having a heart attack. Antonio was told his heart was fine, but he needed to watch his diet. What happened to Antonio?
24.1 Digestive enzymes are produced by the salivary glands, tongue, stomach, pancreas, and small intestine.

24.2 The lamina propria has the following functions: (1) It contains blood vessels and lymphatic vessels, which are the routes by which nutrients are absorbed from the GI tract; (2) it supports the mucosal epithelium and binds it to the muscularis mucosae; and (3) it contains mucosa-associated lymphatic tissue (MALT), which helps protect against disease.

24.3 The neurons of the myenteric plexus regulate GI tract motility, and the neurons of the submucosal plexus regulate GI secretion.

24.4 Mesentery binds the small intestine to the posterior abdominal wall.

24.5 The uvula helps prevent foods and liquids from entering the nasal cavity during swallowing.

24.6 Chloride ions in saliva activate salivary amylase.

24.7 The main component of teeth is connective tissue, specifically dentin.

24.8 The first, second, and third molars do not replace any deciduous teeth.

24.9 The esophageal mucosa and submucosa contain mucus-secreting glands.

24.10 Both. Initiation of swallowing is voluntary and the action is carried out by skeletal muscles. Completion of swallowing—moving a bolus along the esophagus and into the stomach—is involuntary and involves peristalsis by smooth muscle.

24.11 After a large meal, the rugae stretch and disappear as the stomach fills.

24.12 Parietal cells secrete HCl, which is a component of gastric juice. HCl kills microbes in food, denatures proteins, and converts pepsinogen into pepsin.

24.13 Hydrogen ions secreted into gastric juice are derived from carbonic acid (H2CO3).

24.14 The pancreatic duct contains pancreatic juice (fluid and digestive enzymes); the common bile duct contains bile; the hepatopancreatic ampulla contains pancreatic juice and bile.

24.15 The phagocytic cell in the liver is the stellate reticuloendothelial (Kupffer) cell.

24.16 While a meal is being absorbed, nutrients, O2, and certain toxic substances are removed by hepatocytes from blood flowing through liver sinusoids.

24.17 The ileum is the longest part of the small intestine.

24.18 Nutrients being absorbed in the small intestine enter the blood via capillaries or the lymph via lacteals.

24.19 The fluid secreted by duodenal (Brunner’s) glands—alkaline mucus—neutralizes gastric acid and protects the mucosal lining of the duodenum.

24.20 Because monoglycerides are hydrophobic (nonpolar) molecules, they can dissolve in and diffuse through the lipid bilayer of the plasma membrane.

24.21 The stomach and pancreas are the two digestive system organs that secrete the largest volumes of fluid.

24.22 The ascending and descending portions of the colon are retroperitoneal.

24.23 Goblet cells in the large intestine secrete mucus to lubricate colonic contents.

24.24 The pH of gastric juice rises due to the buffering action of some amino acids in food proteins.
METABOLISM, NUTRITION AND HOMEOSTASIS

Metabolic reactions contribute to homeostasis by harvesting chemical energy from consumed nutrients to contribute to the body’s growth, repair, and normal functioning.

Plants use the green pigment chlorophyll to trap energy in sunlight. We don’t have a similarly functioning pigment in our skin, so the food we eat is our only source of energy for running, walking, and even breathing. Many molecules needed to maintain cells and tissues can be made from simpler precursors by the body’s metabolic reactions; others—the essential amino acids, essential fatty acids, vitamins, and minerals—must be obtained from the food we eat. As you learned in Chapter 24, carbohydrates, lipids, and proteins in food are digested by enzymes and absorbed in the gastrointestinal tract. The products of digestion that reach body cells are monosaccharides, fatty acids, glycerol, monoglycerides, and amino acids. Some minerals and many vitamins are part of enzyme systems that catalyze the breakdown and synthesis of carbohydrates, lipids, and proteins. Food molecules absorbed by the gastrointestinal (GI) tract have three main fates:

1. Most food molecules are used to supply energy for sustaining life processes, such as active transport, DNA replication, protein synthesis, muscle contraction, maintenance of body temperature, and mitosis.
2. Some food molecules serve as building blocks for the synthesis of more complex structural or functional molecules, such as muscle proteins, hormones, and enzymes.
3. Other food molecules are stored for future use. For example, glycogen is stored in liver cells, and triglycerides are stored in adipose cells.

In this chapter we discuss how metabolic reactions harvest the chemical energy stored in foods, how each group of food molecules contributes to the body’s growth, repair, and energy needs, and how heat and energy balance is maintained in the body. Finally, we explore some aspects of nutrition to discover why you should opt for fish instead of a burger the next time you eat out.
Metabolic Reactions

Objectives

- Define metabolism.
- Explain the role of ATP in anabolism and catabolism.

Metabolism (me-TAB-ō-lizm; meta- = change) refers to all of the chemical reactions that occur in the body. There are two types of metabolism: catabolism and anabolism. Those chemical reactions that break down complex organic molecules into simpler ones are collectively known as catabolism (ka-TAB-ō-lizm; cata- = downward). Overall, catabolic (decomposition) reactions are exergonic; they provide more energy than they consume, releasing the chemical energy stored in organic molecules. Important sets of catabolic reactions occur in glycolysis, the Krebs cycle, and the electron transport chain, each of which will be discussed later in the chapter.

Chemical reactions that combine simple molecules and monomers to form the body’s complex structural and functional components are collectively known as anabolism (a-NAB-ō-lizm; ana- = upward). Examples of anabolic reactions are the formation of peptide bonds between amino acids during protein synthesis, the building of fatty acids into phospholipids that form the plasma membrane bilayer, and the linkage of glucose monomers to form glycogen. Anabolic reactions are endergonic; they consume more energy than they produce.

Metabolism is an energy-balancing act between catabolic (decomposition) reactions, and anabolic (synthesis) reactions. The molecule that participates most often in energy exchanges in living cells is ATP (adenosine triphosphate), which couples energy-releasing catabolic reactions to energy-requiring anabolic reactions.

The metabolic reactions that occur depend on which enzymes are active in a particular cell at a particular time, or even in a particular part of the cell. Catabolic reactions can be occurring in the mitochondria of a cell at the same time as anabolic reactions are taking place in the endoplasmic reticulum.

A molecule synthesized in an anabolic reaction has a limited lifetime. With few exceptions, it will eventually be broken down and its component atoms recycled into other molecules or excreted from the body. Recycling of biological molecules occurs continuously in living tissues, more rapidly in some than in others. Individual cells may be refurbished molecule by molecule, or a whole tissue may be rebuilt cell by cell.

Coupling of Catabolism and Anabolism by ATP

The chemical reactions of living systems depend on the efficient transfer of manageable amounts of energy from one molecule to another. The molecule that most often performs this task is ATP, the “energy currency” of a living cell. Like money, it is readily available to “buy” cellular activities; it is spent and earned over and over. A typical cell has about a billion molecules of ATP, each of which typically lasts for less than a minute before being used. Thus, ATP is not a long-term-storage form of currency.

Like money, it is readily available to “buy” cellular activities; it is spent and earned over and over. A typical cell has about a billion molecules of ATP, each of which typically lasts for less than a minute before being used. Thus, ATP is not a long-term-storage form of currency.

About 40% of the energy released in catabolism is used for cellular functions; the rest is converted to heat, some of which helps maintain normal body temperature. Excess heat is lost to the environment. Compared with machines, which typically convert only 10–20% of energy into work, the 40% efficiency of the body’s metabolism is impressive. Still, the body has a continuous need to take in and process external sources of energy so that cells can synthesize enough ATP to sustain life.

Checkpoint

1. What is metabolism? Distinguish between anabolism and catabolism, and give examples of each.
2. How does ATP link anabolism and catabolism?

Figure 25.1 Role of ATP in linking anabolic and catabolic reactions. When complex molecules and polymers are split apart (catabolism, at left), some of the energy is transferred to form ATP and the rest is given off as heat. When simple molecules and monomers are combined to form complex molecules (anabolism, at right), ATP provides the energy for synthesis, and again some energy is given off as heat.
ENERGY TRANSFER

**OBJECTIVES**

- Describe oxidation–reduction reactions.
- Explain the role of ATP in metabolism.

Various catabolic reactions transfer energy into the “high-energy” phosphate bonds of ATP. Although the amount of energy in these bonds is not exceptionally large, it can be released quickly and easily. Before discussing metabolic pathways, it is important to understand how this transfer of energy occurs. Two important aspects of energy transfer are oxidation–reduction reactions and mechanisms of ATP generation.

**Oxidation–Reduction Reactions**

**Oxidation** is the removal of electrons from an atom or molecule; the result is a decrease in the potential energy of the atom or molecule. Because most biological oxidation reactions involve the loss of hydrogen atoms, they are called dehydrogenation reactions. An example of an oxidation reaction is the conversion of lactic acid into pyruvic acid:

\[
\begin{array}{c}
\text{COOH} \\
\text{H} - \text{C} \rightarrow \text{OH} \\
\text{CH}_3
\end{array} \xrightarrow{\text{Oxidation}} \begin{array}{c}
\text{COOH} \\
\text{C} = \text{O} \\
\text{CH}_3
\end{array}
\]

Lactic acid \[\text{Remove } 2\text{H}(\text{H}^+)\]\[Pyruvic acid

In the preceding reaction, \(2\text{H}(\text{H}^+)\) means that two neutral hydrogen atoms (\(2\text{H}\)) are removed as one hydrogen ion (\(\text{H}^+\)) plus one hydride ion (\(\text{H}^-\)).

**Reduction** is the opposite of oxidation; it is the addition of electrons to a molecule. Reduction results in an increase in the potential energy of the molecule. An example of a reduction reaction is the conversion of pyruvic acid into lactic acid:

\[
\begin{array}{c}
\text{COOH} \\
\text{C} = \text{O} \\
\text{CH}_3
\end{array} \xrightarrow{\text{Reduction}} \begin{array}{c}
\text{COOH} \\
\text{H} - \text{C} \rightarrow \text{OH} \\
\text{CH}_3
\end{array}
\]

Pyruvic acid \[\text{Add } 2\text{H}(\text{H}^+)\]\[Lactic acid

When a substance is oxidized, the liberated hydrogen atoms do not remain free in the cell but are transferred immediately by coenzymes to another compound. Two coenzymes are commonly used by animal cells to carry hydrogen atoms: nicotinamide adenine dinucleotide (NAD), a derivative of the B vitamin niacin, and flavin adenine dinucleotide (FAD), a derivative of vitamin B₂ (riboflavin). The oxidation and reduction states of NAD⁺ and FAD can be represented as follows:

\[
\begin{align*}
\text{NAD}^+ & \xrightarrow{+ 2\text{H}(\text{H}^+)} \text{NADH} + \text{H}^+ \\
\text{Oxidized} & \text{Reduced} \\
\text{FAD} & \xrightarrow{+ 2\text{H}(\text{H}^+)} \text{FADH}_2 \\
\text{Oxidized} & \text{Reduced}
\end{align*}
\]

When NAD⁺ is reduced to NADH + H⁺, the NAD⁺ gains a hydride ion (\(\text{H}^-\)), neutralizing its charge, and the \(\text{H}^+\) is released into the surrounding solution. When NADH is oxidized to NAD⁺, the loss of the hydride ion results in one less hydrogen atom and an additional positive charge. FAD is reduced to FADH₂ when it gains a hydrogen ion and a hydride ion, and FADH₂ is oxidized to FAD when it loses the same two ions.

Oxidation and reduction reactions are always coupled; each time one substance is oxidized, another is simultaneously reduced. Such paired reactions are called **oxidation–reduction** or **redox reactions**. For example, when lactic acid is oxidized to form pyruvic acid, the two hydrogen atoms removed in the reaction are used to remove NAD⁺.

An important point to remember about oxidation–reduction reactions is that oxidation is usually an exergonic (energy-releasing) reaction. Cells use multistep biochemical reactions to release energy from energy-rich, highly reduced compounds (with many hydrogen atoms) to lower-energy, highly oxidized compounds (with many oxygen atoms or multiple bonds). For example, when a cell oxidizes a molecule of glucose (\(\text{C}_6\text{H}_{12}\text{O}_6\)), the energy in the glucose molecule is removed in a stepwise manner. Ultimately, some of the energy is captured by transferring it to ATP, which then serves as an energy source for energy-requiring reactions within the cell. Compounds with many hydrogen atoms such as glucose contain more chemical potential energy than oxidized compounds. For this reason, glucose is a valuable nutrient.

**Mechanisms of ATP Generation**

Some of the energy released during oxidation reactions is captured within a cell when ATP is formed. Briefly, a phosphate group ([P]) is added to ADP, with an input of energy, to form ATP. The two high-energy phosphate bonds that can be used to transfer energy are indicated by “squiggles” (~):

\[
\text{Adenosine} \overset{[P]}{-} \overset{[P]}{-} \overset{+ \text{energy}}{\rightarrow} \text{ADP}
\]

\[
\text{Adenosine} \overset{[P]}{-} \overset{[P]}{-} \overset{\text{ATP}}{\rightarrow}
\]

The high-energy phosphate bond that attaches the third phosphate group contains the energy stored in this reaction. The addition of a phosphate group to a molecule, called **phosphorylation** (fos’-for-i-LA-shun), increases its potential energy. Organisms use three mechanisms of phosphorylation to generate ATP:

1. **Substrate-level phosphorylation** generates ATP by transferring a high-energy phosphate group from an intermediate phosphorylated metabolic compound—a substrate—directly to ADP. In human cells, this process occurs in the cytosol.
Oxygen ($O_2$). This process occurs in the inner mitochondrial membrane of cells.

2. **Oxidative phosphorylation** removes electrons from organic compounds and passes them through a series of electron acceptors, called the electron transport chain, to molecules of oxygen ($O_2$). This process occurs in the inner mitochondrial membrane of cells.

3. **Photophosphorylation** occurs only in chlorophyll-containing plant cells or in certain bacteria that contain other light-absorbing pigments.

**CHECKPOINT**

3. How is a hydride ion different from a hydrogen ion?
   - What is the involvement of both ions in redox reactions?
   4. What are three ways that ATP can be generated?

**CARBOHYDRATE METABOLISM**

- Describe the fate, metabolism, and functions of carbohydrates.

As you learned in Chapter 24, both polysaccharides and disaccharides are hydrolyzed into the monosaccharides glucose (about 80%), fructose, and galactose during the digestion of carbohydrates. (Some fructose is converted into glucose as it is absorbed through the intestinal epithelial cells.) Hepatocytes (liver cells) convert most of the remaining fructose and practically all the galactose to glucose. So the story of carbohydrate metabolism is really the story of glucose metabolism. Because negative feedback systems maintain blood glucose at about 90 mg/100 mL of plasma (5 mmol/liter), a total of 2–3 g of glucose normally circulates in the blood.

**The Fate of Glucose**

Because glucose is the body’s preferred source for synthesizing ATP, its use depends on the needs of body cells, which include the following:

- **ATP production.** In body cells that require immediate energy, glucose is oxidized to produce ATP. Glucose not needed for immediate ATP production can enter one of several other metabolic pathways.

- **Amino acid synthesis.** Cells throughout the body can use glucose to form several amino acids, which then can be incorporated into proteins.

- **Glycogen synthesis.** Hepatocytes and muscle fibers can perform glycogenesis (glyko-genesis; glycogen = sugar or sweet; -genesis = to generate), in which hundreds of glucose monomers are combined to form the polysaccharide glycogen. Total storage capacity of glycogen is about 125 g in the liver and 375 g in skeletal muscles.

- **Triglyceride synthesis.** When the glycogen storage areas are filled up, hepatocytes can transform the glucose to glyceral and fatty acids that can be used for lipogenesis (lipo-genesis; triglyceride synthesis). Triglycerides then are deposited in adipose tissue, which has virtually unlimited storage capacity.

**Glucose Movement into Cells**

Before glucose can be used by body cells, it must first pass through the plasma membrane and enter the cytosol. Glucose absorption in the gastrointestinal tract (and kidney tubules) is accomplished via secondary active transport (Na$^+$-glucose symporters). Glucose entry into most other body cells occurs via GluT molecules, a family of transporters that bring glucose into cells via facilitated diffusion (see page 69). A high level of insulin increases the insertion of one type of GluT, called GluT4, into the plasma membranes of most body cells, thereby increasing the rate of facilitated diffusion of glucose into cells. In neurons and hepatocytes, however, another type of GluT is always present in the plasma membrane, so glucose entry is always “turned on.” Upon entering a cell, glucose becomes phosphorylated. Because GluT cannot transport phosphorylated glucose, this reaction traps glucose within the cell.

**Glucose Catabolism**

The oxidation of glucose to produce ATP is also known as **cellular respiration**, and it involves four sets of reactions: glycolysis, the formation of acetyl coenzyme A, the Krebs cycle, and the electron transport chain (Figure 25.2).

1. **Glycolysis** is a set of reactions in which one glucose molecule is oxidized and two molecules of pyruvic acid are produced. The reactions also produce two molecules of ATP and two energy-containing NADH + H$^+$. Because glycolysis does not require oxygen, it is a way to produce ATP anaerobically (without oxygen) and is known as **anaerobic cellular respiration** (an-ar-ó-bik; an- = not; aer- = air; -bios = life).

2. **Formation of acetyl coenzyme A** is a transition step that prepares pyruvic acid for entrance into the Krebs cycle. This step also produces energy-containing NADH + H$^+$ plus carbon dioxide (CO$_2$).

3. **Krebs cycle reactions** oxidize acetyl coenzyme A and produce CO$_2$, ATP, energy-containing NADH + H$^+$, and FADH$_2$.

4. **Electron transport chain reactions** oxidize NADH + H$^+$ and FADH$_2$ and transfer their electrons through a series of electron carriers. The Krebs cycle and the electron transport chain both require oxygen to produce ATP and are collectively known as **aerobic cellular respiration**.

**Glycolysis**

During glycolysis (glyko-ol-i-sis; -lysis = breakdown), chemical reactions split a 6-carbon molecule of glucose into two 3-carbon molecules of pyruvic acid (Figure 25.3). Even though glycolysis consumes two ATP molecules, it produces four ATP molecules, for a net gain of two ATP molecules for each glucose molecule that is oxidized.
**Figure 25.2** Overview of cellular respiration (oxidation of glucose). A modified version of this figure appears in several places in this chapter to indicate the relationships of particular reactions to the overall process of cellular respiration. The oxidation of glucose involves glycolysis, the formation of acetyl coenzyme A, the Krebs cycle, and the electron transport chain.

1. **Glycolysis**
   - 1 Glucose → 2 ATP, 2 NADH + 2 H+, 2 Pyruvic acid

2. **Formation of Acetyl Coenzyme A**
   - 2 Pyruvic acid → 2 Acetyl coenzyme A

3. **Krebs Cycle**
   - 2 Acetyl coenzyme A → 6 CO2 + 6 NADH + 6 H+, 2 FADH2

4. **Electron Transport Chain**
   - Electrons → 32 or 34 ATP
   - 6 O2 → 6 H2O

**Question:** Which of the four processes shown here is also called anaerobic cellular respiration?

**Figure 25.3** Cellular respiration begins with glycolysis. During glycolysis, each molecule of glucose is converted to two molecules of pyruvic acid.

1. **Glycolysis**
   - 1 Glucose → 2 ATP, NADH + H+, 2 Pyruvic acid

2. **Formation of Acetyl Coenzyme A**
   - 2 Pyruvic acid → 2 Acetyl coenzyme A

3. **Krebs Cycle**
   - 2 Acetyl coenzyme A → CO2 + 2 NADH + 2 H+, FADH2

4. **Electron Transport Chain**
   - ATP

**Question:** For each glucose molecule that undergoes glycolysis, how many ATP molecules are generated?
The carboxyl groups (—COOH) of intermediates in glycolysis and in the citric acid cycle are mostly ionized at the pH of body fluids to —COO\(^{−}\). The suffix "-ic acid" indicates the non-ionized form, whereas the ending "-ate" indicates the ionized form. Although the "-ate" names are more correct, we will use the "acid" names because these terms are more familiar.
Figure 25.4 shows the 10 reactions that comprise glycolysis. In the first half of the sequence (reactions 1 through 5), energy in the form of ATP is “invested” and the 6-carbon glucose is split into two 3-carbon molecules of glyceraldehyde 3-phosphate. Phosphofructokinase, the enzyme that catalyzes step 3, is the key regulator of the rate of glycolysis. The activity of this enzyme is high when ADP concentration is high, in which case ATP is produced rapidly. When the activity of phosphofructokinase is low, most glucose does not enter the reactions of glycolysis but instead undergoes conversion to glycogen for storage. In the second half of the sequence (reactions 6 through 10), the two glyceraldehyde 3-phosphate molecules are converted to two pyruvic acid molecules and ATP is generated.

The Fate of Pyruvic Acid

The fate of pyruvic acid produced during glycolysis depends on the availability of oxygen (Figure 25.5). If oxygen is scarce (anaerobic conditions)—for example, in skeletal muscle fibers during strenuous exercise—then pyruvic acid is reduced via an anaerobic pathway by the addition of two hydrogen atoms to form lactate:

\[
2 \text{Pyruvic acid} + 2 \text{NAD}^+ + 2 \text{H}^+ \rightarrow 2 \text{Lactic acid} + 2 \text{NADH} + 2 \text{H}^+
\]

This reaction regenerates the NAD\(^+\) that was used in the oxidation of glyceraldehyde 3-phosphate (see step 6 in Figure 25.4) and thus allows glycolysis to continue. As lactate is produced, it rapidly diffuses out of the cell and enters the blood. Hepatocytes remove lactic acid from the blood and convert it back to pyruvic acid. Recall that buildup of lactic acid is one factor that contributes to muscle fatigue.

When oxygen is plentiful (aerobic conditions), most cells convert pyruvic acid to acetyl coenzyme A. This molecule links glycolysis, which occurs in the cytosol, with the Krebs cycle, which occurs in the matrix of mitochondria. Pyruvic acid enters the mitochondrial matrix with the help of a special transporter protein. Because they lack mitochondria, red blood cells can only produce ATP through glycolysis.

Formation of Acetyl Coenzyme A

Each step in the oxidation of glucose requires a different enzyme, and often a coenzyme as well. The coenzyme used at this point in cellular respiration is coenzyme A (CoA), which is derived from pantothenic acid, a B vitamin. During the transitional step between glycolysis and the Krebs cycle, pyruvic acid is prepared for entrance into the cycle. The enzyme pyruvate dehydrogenase, which is located exclusively in the mitochondrial matrix, converts pyruvic acid to a two-carbon fragment called an acetyl group by removing a molecule of carbon dioxide (Figure 25.5). The loss of a molecule of CO\(_2\) by a substance is called decarboxylation (dé-kar-bok'-si-LÁ-shun). This is the first reaction in cellular respiration that releases CO\(_2\). During this reaction, pyruvic acid is also oxidized. Each pyruvic acid loses two hydrogen atoms in the form of one hydride ion (H\(^-\)) plus one hydrogen ion (H\(^+\)). The coenzyme NAD\(^+\) is reduced as it picks up the H\(^-\) from pyruvic acid; the H\(^+\) is released into the mitochondrial matrix. The reduction of NAD\(^+\) to NADH + H\(^+\) is indicated in Figure 25.5 by the curved arrow entering and then leaving the reaction. Recall that the oxidation of one glucose molecule produces two molecules of pyruvic acid, so for each molecule of glucose, two molecules of carbon dioxide are lost and two NADH + H\(^+\) are produced. The acetyl group attaches to coenzyme A, producing a molecule called acetyl coenzyme A (acetyl CoA).

Figure 25.5 Fate of pyruvic acid.

When oxygen is plentiful, pyruvic acid enters mitochondria, is converted to acetyl coenzyme A, and enters the Krebs cycle (aerobic pathway). When oxygen is scarce, most pyruvic acid is converted to lactic acid via an anaerobic pathway.
The Krebs Cycle

Once the pyruvic acid has undergone decarboxylation and the remaining acetyl group has attached to CoA, the resulting compound (acetyl CoA) is ready to enter the Krebs cycle (Figure 25.6). The Krebs cycle—named for the biochemist Hans Krebs, who described these reactions in the 1930s—is also known as the citric acid cycle, for the first molecule formed when an acetyl group joins the cycle. The reactions occur in the matrix of mitochondria and consist of a series of oxidation–reduction reactions and decarboxylation reactions that release CO2. In the Krebs cycle, the oxidation–reduction reactions transfer chemical energy, in the form of electrons, to two coenzymes—NAD+ and FAD. The pyruvic acid derivatives are oxidized, and the coenzymes are reduced. In addition, one step generates ATP. Figure 25.7 shows the reactions of the Krebs cycle in more detail.

The reduced coenzymes (NADH and FADH2) are the most important outcome of the Krebs cycle because they contain the energy originally stored in glucose and then in pyruvic acid. Overall, for every acetyl CoA that enters the Krebs cycle, three NADH, three H+, and one FADH2 are produced by oxidation–reduction reactions, and one molecule of ATP is generated by substrate-level phosphorylation (see Figure 25.6). In the electron transport chain, the three NADH + three H+ will later yield nine ATP molecules, and the FADH2 will later yield two ATP molecules. Thus, each “turn” of the Krebs cycle eventually generates 12 molecules of ATP. Because each glucose molecule provides two acetyl CoA molecules, glucose catabolism via the Krebs cycle and the electron transport chain yields 24 molecules of ATP per glucose molecule.

Liberation of CO2 occurs as pyruvic acid is converted to acetyl CoA and during the two decarboxylation reactions of the Krebs cycle (see Figure 25.6). Because each molecule of glucose generates two molecules of pyruvic acid, six molecules of CO2 are liberated from each original glucose molecule catabolized along this pathway. The molecules of CO2 diffuse out of the mitochondria, through the cytosol and plasma membrane, and then into the blood. Blood transports the CO2 to the lungs, where it eventually is exhaled.

Figure 25.6 After formation of acetyl coenzyme A, the next stage of cellular respiration is the Krebs cycle.

Reactions of the Krebs cycle occur in the matrix of mitochondria.

? When in cellular respiration is carbon dioxide given off? What happens to this gas?
Figure 25.7 The eight reactions of the Krebs cycle. 1 Entry of the acetyl group. The chemical bond that attaches the acetyl group to coenzyme A (CoA) breaks, and the two-carbon acetyl group attaches to a four-carbon molecule of oxaloacetic acid to form a six-carbon molecule called citric acid. CoA is free to combine with another acetyl group from pyruvic acid and repeat the process. 2 Isomerization. Citric acid undergoes isomerization to isocitric acid, which has the same molecular formula as citrate. Notice, however, that the hydroxyl group (\(-\text{OH}\)) is attached to a different carbon. 3 Oxidative decarboxylation. Isocitric acid is oxidized and loses a molecule of CO₂, forming alpha-ketoglutaric acid. The H⁺ from the oxidation is passed on to NAD⁺, which is reduced to NADH⁺. 4 Oxidative decarboxylation. Alpha-ketoglutaric acid is oxidized, loses a molecule of CO₂, and picks up CoA to form succinyl CoA. 5 Substrate-level phosphorylation. CoA is displaced by a phosphate group, which is then transferred to guanosine diphosphate (GDP) to form guanosine triphosphate (GTP). GTP can donate a phosphate group to ADP to form ATP. 6 Dehydrogenation. Succinic acid is oxidized to fumaric acid as two of its hydrogen atoms are transferred to the coenzyme flavin adenine dinucleotide (FAD), which is reduced to FADH₂. 7 Hydration. Fumaric acid is converted to malic acid by the addition of a molecule of water. 8 Dehydrogenation. In the final step in the cycle, malic acid is oxidized to re-form oxaloacetic acid. Two hydrogen atoms are removed and one is transferred to NAD⁺, which is reduced to NADH⁺. The regenerated oxaloacetic acid can combine with another molecule of acetyl CoA, beginning a new cycle.

The three main results of the Krebs cycle are the production of reduced coenzymes (NADH⁺ and FADH₂), which contain stored energy; the generation of GTP, a high-energy compound that is used to produce ATP; and the formation of CO₂, which is transported to the lungs and exhaled.

Why is the production of reduced coenzymes important in the Krebs cycle?
The Electron Transport Chain

The electron transport chain is a series of electron carriers, integral membrane proteins in the inner mitochondrial membrane. This membrane is folded into cristae that increase its surface area, accommodating thousands of copies of the transport chain in each mitochondrion. Each carrier in the chain is reduced as it picks up electrons and oxidized as it gives up electrons. As electrons pass through the chain, a series of exergonic reactions release small amounts of energy; this energy is used to form ATP. In aerobic cellular respiration, the final electron acceptor of the chain is oxygen. Because this mechanism of ATP generation links chemical reactions (the passage of electrons along the transport chain) with the pumping of hydrogen ions, it is called chemiosmosis (chemi- = chemical; osmosis = pushing). Briefly, chemiosmosis works as follows (Figure 25.8):

1. Energy from NADH + H⁺ passes along the electron transport chain and is used to pump H⁺ from the matrix of the mitochondrion into the space between the inner and outer mitochondrial membranes. This mechanism is called a proton pump because H⁺ ions consist of a single proton.
2. A high concentration of H⁺ accumulates between the inner and outer mitochondrial membranes.
3. ATP synthesis then occurs as hydrogen ions flow back into the mitochondrial matrix through a special type of H⁺ channel in the inner membrane.

**Electron Carriers** Several types of molecules and atoms serve as electron carriers:
- Flavin mononucleotide (FMN) is a flavoprotein derived from riboflavin (vitamin B₂).
- Cytochromes (Si-tō-kromz) are proteins with an iron-containing group (heme) capable of existing alternately in a reduced form (Fe²⁺) and an oxidized form (Fe³⁺). The cytochromes involved in the electron transport chain include cytochrome b (cyt b), cytochrome c₁ (cyt c₁), cytochrome c (cyt c), cytochrome a (cyt a), and cytochrome a₃ (cyt a₃).
- Iron-sulfur (Fe-S) centers contain either two or four iron atoms bound to sulfur atoms that form an electron transfer center within a protein.
- Copper (Cu) atoms bound to two proteins in the chain also participate in electron transfer.
- Coenzyme Q, symbolized Q, is a nonprotein, low-molecular-weight carrier that is mobile in the lipid bilayer of the inner membrane.

**Steps in Electron Transport and Chemiosmotic ATP Generation** Within the inner mitochondrial membrane, the carriers of the electron transport chain are clustered into three complexes, each of which acts as a proton pump that expels H⁺ from the mitochondrial matrix and helps create an electrochemical gradient of H⁺. Each of the three proton pumps transports electrons and pumps H⁺, as shown in Figure 25.9. Notice that oxygen is used to help form water in step 4. This is the only point in aerobic cellular respiration where O₂ is consumed. Cyanide is a deadly poison because it binds to the cytochrome oxidase complex and blocks this last step in electron transport. The pumping of H⁺ produces both a concentration gradient of protons and an electrical gradient. The buildup of H⁺ makes one side of the inner mitochondrial membrane positively charged compared with the other side. The resulting electrochemical gradient has potential energy, called the proton motive force. Proton channels in the inner mitochondrial membrane allow H⁺ to flow back across the membrane, driven by the proton motive force. As H⁺ flow back, they generate ATP because the H⁺ channels also include an enzyme called ATP synthase. The enzyme uses the proton motive force to synthesize ATP from ADP and P. The process of chemiosmosis is responsible for most of the ATP produced during cellular respiration.
Figure 25.9  The actions of the three proton pumps and ATP synthase in the inner membrane of mitochondria. Each pump is a complex of three or more electron carriers. 1 The first proton pump is the NADH dehydrogenase complex, which contains flavin mononucleotide (FMN) and five or more Fe-S centers. NADH + H⁺ is oxidized to NAD⁺, and FMN is reduced to FMNH₂, which in turn is oxidized as it passes electrons to the iron–sulfur centers. Q, which is mobile in the membrane, shuttles electrons to the second pump complex. 2 The second proton pump is the cytochrome b-c₁ complex, which contains cytochromes and an iron–sulfur center. Electrons are passed successively from Q to cyt b, to Fe–S, to cyt c₁. The mobile shuttle that passes electrons from the second pump complex to the third is cytochrome c (cyt c). 3 The third proton pump is the cytochrome oxidase complex, which contains cytochromes a and a₃ and two copper atoms. Electrons pass from cyt c, to Cu, to cyt a, and finally to cyt a₃. Cyt a₃ passes its electrons to one-half of a molecule of oxygen (O₂), which becomes negatively charged and then picks up two H⁺ from the surrounding medium to form H₂O. As the three proton pumps pass electrons from one carrier to the next, they also move protons (H⁺) from the matrix into the space between the inner and outer mitochondrial membranes. As protons flow back into the mitochondrial matrix through the H⁺ channel in ATP synthase, ATP is synthesized.

Where is the concentration of H⁺ highest?

Summary of Cellular Respiration
The various electron transfers in the electron transport chain generate either 32 or 34 ATP molecules from each molecule of glucose that is oxidized: either 28 or 30* from the 10 molecules of NADH + H⁺ and two from each of the two molecules of FADH₂ (four total). Thus, during cellular respiration, 36 or 38 ATPs can be generated from one molecule of glucose. Note that two of those ATPs come from substrate-level phosphorylation in glycolysis, and two come from substrate-level phosphorylation in the Krebs cycle. The overall reaction is:

\[ C_6H_{12}O_6 + 6 O_2 + 36 \text{ or } 38 \text{ ADPs } + 36 \text{ or } 38 \text{ P } \rightarrow 6 \text{ CO}_2 + 6 \text{ H}_2\text{O} + 36 \text{ or } 38 \text{ ATPs} \]

Table 25.1 summarizes the ATP yield during cellular respiration. A schematic depiction of the principal reactions of cellular respiration is presented in Figure 25.10. The actual ATP yield may be lower than 36 or 38 ATPs per glucose. One uncertainty is the exact number of H⁺ that must be pumped out to generate one ATP during chemiosmosis. In addition, the ATP generated in mitochondria must be transported out of these organelles into the cytosol for use elsewhere in a cell. Exporting ATP in exchange for the inward movement of ADP formed from metabolic reactions in the cytosol uses up part of the proton motive force.

*The two NADH produced in the cytosol during glycolysis cannot enter mitochondria. Instead, they donate their electrons to one of two transfer molecules, known as the malate shuttle and the glycerol phosphate shuttle. In cells of the liver, kidneys, and heart, use of the malate shuttle results in three ATPs synthesized for each NADH. In other body cells, such as skeletal muscle fibers and neurons, use of the glycerol phosphate shuttle results in two ATPs synthesized for each NADH.
Glycolysis, the Krebs cycle, and especially the electron transport chain provide all the ATP for cellular activities. Because the Krebs cycle and electron transport chain are aerobic processes, cells cannot carry on their activities for long if oxygen is lacking.

**Glucose Anabolism**

Even though most of the glucose in the body is catabolized to generate ATP, glucose may take part in or be formed via several anabolic reactions. One is the synthesis of glycogen; another is the synthesis of new glucose molecules from some of the products of protein and lipid breakdown.

**Glucose Storage: Glycogenesis**

If glucose is not needed immediately for ATP production, it combines with many other molecules of glucose to form glycogen, a polysaccharide that is the only stored form of carbohydrate in our bodies. The hormone insulin, from pancreatic beta cells, stimulates hepatocytes and skeletal muscle cells to carry out glycogenesis, the synthesis of glycogen (Figure 25.11). The body can store about 500 g (about 1.1 lb) of glycogen, roughly 75% in skeletal muscle fibers and the rest in liver cells. During glycogenesis, glucose is first phosphorylated to glucose 6-phosphate by hexokinase. Glucose 6-phosphate is converted to glucose 1-phosphate, then to uridine diphosphate glucose, and finally to glycogen.

**Glucose Release: Glycogenolysis**

When body activities require ATP, glycogen stored in hepatocytes is broken down into glucose and released into the blood.
to be transported to cells, where it will be catabolized by the processes of cellular respiration already described. The process of splitting glycogen into its glucose subunits is called **glycogenolysis** (gli̱-kō-je-NOL-e-sis). (Note: Do not confuse glycogenolysis, which is the breakdown of glycogen to glucose, with glycolysis, the 10 reactions that convert glucose to pyruvic acid.)

Glycogenolysis is not a simple reversal of the steps of glycogenesis (Figure 25.11). It begins by splitting glucose molecules off the branched glycogen molecule via phosphorylation to form glucose 1-phosphate. Phosphorylase, the enzyme that catalyzes this reaction, is activated by glucagon from pancreatic alpha cells and epinephrine from the adrenal medulla. Glucose 1-phosphate is then converted to glucose 6-phosphate and finally to glucose, which leaves hepatocytes via glucose transporters (GluT) in the plasma membrane. Phosphorylated glucose molecules cannot ride aboard the GluT transporters, however, and phosphatase, the enzyme that converts glucose 6-phosphate into glucose, is absent in skeletal muscle cells. Thus, hepatocytes, which have phosphatase, can release glucose derived from glycogen to the bloodstream, but skeletal muscle cells cannot. In skeletal muscle cells, glycogen is broken down into glucose 1-phosphate, which is then catabolized for ATP production via glycolysis and the Krebs cycle. However, the lactic acid produced by glycolysis in muscle cells can be converted to glucose in the liver. In this way, muscle glycogen can be an indirect source of blood glucose.

**Formation of Glucose from Proteins and Fats:** 

**Gluconeogenesis**

When your liver runs low on glycogen, it is time to eat. If you don’t, your body starts catabolizing triglycerides (fats) and proteins. Actually, the body normally catabolizes some of its triglycerides and proteins, but large-scale triglyceride and protein catabolism does not happen unless you are starving, eating very few carbohydrates, or suffering from an endocrine disorder.

The glycerol part of triglycerides, lactic acid, and certain amino acids can be converted in the liver to glucose (Figure 25.12). The process by which glucose is formed from these non-carbohydrate sources is called **gluconeogenesis** (gloo'-kō-nē'-ō-).
JEN-e-sis; neo = new). An easy way to distinguish this term from glycogenesis or glycogenolysis is to remember that in this case glucose is not converted back from glycogen, but is instead newly formed. About 60% of the amino acids in the body can be used for gluconeogenesis. Lactic acid and amino acids such as alanine, cysteine, glycine, serine, and threonine, are converted to pyruvic acid, which then may be synthesized into glucose or enter the Krebs cycle. Glycerol may be converted into glyceraldehyde 3-phosphate, which may form pyruvic acid or be used to synthesize glucose.

Gluconeogenesis is stimulated by cortisol, the main glucocorticoid hormone of the adrenal cortex, and by glucagon from the pancreas. In addition, cortisol stimulates the breakdown of proteins into amino acids, thus expanding the pool of amino acids available for gluconeogenesis. Thyroid hormones (thyroxine and triiodothyronine) also mobilize proteins and may mobilize triglycerides from adipose tissue, thereby making glycerol available for gluconeogenesis.

**CHECKPOINT**

5. How does glucose move into or out of body cells?
6. What happens during glycolysis?
7. How is acetyl coenzyme A formed?
8. Outline the principal events and outcomes of the Krebs cycle.
9. What happens in the electron transport chain and why is this process called chemiosmosis?
10. Which reactions produce ATP during the complete oxidation of a molecule of glucose?
11. Under what circumstances do glycogenesis and glycogenolysis occur?
12. What is gluconeogenesis, and why is it important?

**LIPID METABOLISM**

**OBJECTIVES**

- Describe the lipoproteins that transport lipids in the blood.
- Describe the fate, metabolism, and functions of lipids.

**Transport of Lipids by Lipoproteins**

Most lipids, such as triglycerides, are nonpolar and therefore very hydrophobic molecules. They do not dissolve in water. To be transported in watery blood, such molecules first must be made more water-soluble by combining them with proteins produced by the liver and intestine. The lipid and protein combinations thus formed are lipoproteins, spherical particles with an outer shell of proteins, phospholipids, and cholesterol molecules surrounding an inner core of triglycerides and other lipids (Figure 25.13). The proteins in the outer shell are called apoproteins (apo) and are designated by the letters A, B, C, D, and E plus a number. In addition to helping solubilize the lipoprotein in body fluids, each apoprotein has specific functions.

Each of the several types of lipoproteins has different functions, but all essentially are transport vehicles. They provide delivery and pickup services so that lipids can be available when cells need them or removed from circulation when they are not needed. Lipoproteins are categorized and named mainly according to their density, which varies with the ratio of lipids (which have a low density) to proteins (which have a high density). From largest and lightest to smallest and heaviest, the four major classes of lipoproteins are chylomicrons, very low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs).

Chylomicrons, which form in mucosal epithelial cells of the small intestine, transport dietary (ingested) lipids to adipose tissue for storage. They contain about 1–2% proteins, 85% triglycerides, 7% phospholipids, and 6–7% cholesterol, plus a small amount of fat-soluble vitamins. Chylomicrons enter lacteals of intestinal villi and are carried by lymph into venous blood and then into the systemic circulation. Their presence gives blood plasma a milky appearance, but they remain in the blood for only a few minutes. As chylomicrons circulate through the capillaries of adipose tissue, one of their apoproteins, apo C-2, activates endothelial lipoprotein lipase, an enzyme that removes fatty acids from chylomicron triglycerides. The free fatty acids are then taken up by adipocytes for synthesis and storage as triglycerides and by muscle cells for ATP production. Hepatocytes remove chylomicron remnants from the blood via receptor-mediated endocytosis, in which another chylomicron apoprotein, apo E, is the docking protein.

![Figure 25.13 A lipoprotein. Shown here is a VLDL.](image-url)
Very low-density lipoproteins (VLDLs), which form in hepatocytes, contain mainly endogenous (made in the body) lipids. VLDLs contain about 10% proteins, 50% triglycerides, 20% phospholipids, and 20% cholesterol. VLDLs transport triglycerides synthesized in hepatocytes to adipocytes for storage. Like chylomicrons, they lose triglycerides as their apo C-2 activates endothelial lipoprotein lipase, and the resulting fatty acids are taken up by adipocytes for storage and by muscle cells for ATP production. As they deposit some of their triglycerides in adipose cells, VLDLs are converted to LDLs.

Low-density lipoproteins (LDLs) contain 25% proteins, 5% triglycerides, 20% phospholipids, and 50% cholesterol. They carry about 75% of the total cholesterol in blood and deliver it to cells throughout the body for use in repair of cell membranes and synthesis of steroid hormones and bile salts. LDLs contain a single apoprotein, apo B100, which is the docking protein that binds to LDL receptors on the plasma membrane of body cells so that LDL can enter the cell via receptor-mediated endocytosis. Within the cell, the LDL is broken down, and the cholesterol is released to serve the cell’s needs. Once a cell has sufficient cholesterol for its activities, a negative feedback system inhibits the cell’s synthesis of new LDL receptors.

When present in excessive numbers, LDLs also deposit cholesterol in and around smooth muscle fibers in arteries, forming fatty plaques that increase the risk of coronary artery disease (see page 750). For this reason, the cholesterol in LDLs, called LDL-cholesterol, is known as “bad” cholesterol. Because some people have too few LDL receptors, their body cells remove LDL from the blood less efficiently; as a result, their plasma LDL level is abnormally high, and they are more likely to develop fatty plaques. Eating a high-fat diet increases the production of VLDLs, which elevates the LDL level and increases the formation of fatty plaques.

High-density lipoproteins (HDLs), which contain 40–45% proteins, 5–10% triglycerides, 30% phospholipids, and 20% cholesterol, remove excess cholesterol from body cells and the blood and transport it to the liver for elimination. Because HDLs prevent accumulation of cholesterol in the blood, a high HDL level is associated with decreased risk of coronary artery disease. For this reason, HDL-cholesterol is known as “good” cholesterol.

Sources and Significance of Blood Cholesterol

There are two sources of cholesterol in the body. Some is present in foods (eggs, dairy products, organ meats, beef, pork, and processed luncheon meats), but most is synthesized by hepatocytes. Fatty foods that don’t contain any cholesterol at all can still dramatically increase blood cholesterol level in two ways. First, a high intake of dietary fats stimulates reabsorption of cholesterol-containing bile back into the blood, so less cholesterol is lost in the feces. Second, when saturated fats are broken down in the body, hepatocytes use some of the breakdown products to make cholesterol.

A lipid profile test usually measures total cholesterol (TC), HDL-cholesterol, and triglycerides (VLDLs). LDL-cholesterol then is calculated by using the following formula: LDL-cholesterol = TC – HDL-cholesterol – (triglycerides/5). In the United States, blood cholesterol is usually measured in milligrams per deciliter (mg/dL); a deciliter is 0.1 liter or 100 mL. For adults, desirable levels of blood cholesterol are total cholesterol under 200 mg/dL, LDL-cholesterol under 130 mg/dL, and HDL-cholesterol over 40 mg/dL. Normally, triglycerides are in the range of 10–190 mg/dL.

As total cholesterol level increases, the risk of coronary artery disease begins to rise. When total cholesterol is above 200 mg/dL (5.2 mmol/liter), the risk of a heart attack doubles with every 50 mg/dL (1.3 mmol/liter) increase in total cholesterol. Total cholesterol of 200–239 mg/dL and LDL of 130–159 mg/dL are borderline-high; total cholesterol above 239 mg/dL and LDL above 159 mg/dL are classified as high blood cholesterol. The ratio of total cholesterol to HDL-cholesterol predicts the risk of developing coronary artery disease. For example, a person with a total cholesterol of 180 mg/dL and HDL of 60 mg/dL has a ratio of 3. Ratios above 4 are considered undesirable; the higher the ratio, the greater the risk of developing coronary artery disease.

Among the therapies used to reduce blood cholesterol level are exercise, diet, and drugs. Regular physical activity at aerobic and nearly aerobic levels raises HDL level. Dietary changes are aimed at reducing the intake of total fat, saturated fats, and cholesterol. Drugs used to treat high blood cholesterol levels include cholestyramine (Questran) and colestipol (Colestid), which promote excretion of bile in the feces; nicotinic acid (Liponicin); and the “statin” drugs—atorvastatin (Lipitor), lovastatin (Mevacor), and simvastatin (Zocor), which block the key enzyme (HMG-CoA reductase) needed for cholesterol synthesis.

The Fate of Lipids

Lipids, like carbohydrates, may be oxidized to produce ATP. If the body has no immediate need to use lipids in this way, they are stored in adipose tissue (fat depots) throughout the body and in the liver. A few lipids are used as structural molecules or to synthesize other essential substances. Some examples include phospholipids, which are components of plasma membranes; lipoproteins, which are used to transport cholesterol throughout the body; thromboplastin, which is needed for blood clotting; and myelin sheaths, which speed up nerve impulse conduction. Two essential fatty acids that the body cannot synthesize are linoleic acid and linolenic acid. Dietary sources include vegetable oils and leafy vegetables. The various functions of lipids in the body may be reviewed in Table 2.7 on page 46.

Triglyceride Storage

A major function of adipose tissue is to remove triglycerides from chylomicrons and VLDLs and store them until they are needed for ATP production in other parts of the body.
Triglycerides stored in adipose tissue constitute 98% of all body energy reserves. They are stored more readily than glycogen, in part because triglycerides are hydrophobic and do not exert osmotic pressure on cell membranes. Adipose tissue also insulates and protects various parts of the body. Adipocytes in the subcutaneous layer contain about 50% of the stored triglycerides. Other adipose tissues account for the other half: about 12% around the kidneys, 10–15% in the omenta, 15% in genital areas, 5–8% between muscles, and 5% behind the eyes, in the sulci of the heart, and attached to the outside of the large intestine. Triglycerides in adipose tissue are continually broken down and resynthesized. Thus, the triglycerides stored in adipose tissue today are not the same molecules that were present last month because they are continually released from storage, transported in the blood, and redeposited in other adipose tissue cells.

Lipid Catabolism: Lipolysis

In order for muscle, liver, and adipose tissue to oxidize the fatty acids derived from triglycerides to produce ATP, the triglycerides must first be split into glycerol and fatty acids, a process called lipolysis (li-POL-i-sis). Lipolysis is catalyzed by enzymes called lipases. Epinephrine and norepinephrine enhance triglyceride breakdown into fatty acids and glycerol. These hormones are released when sympathetic tone increases, as occurs, for example, during exercise. Other lipolytic hormones include cortisol, thyroid hormones, and insulinlike growth factors. By contrast, insulin inhibits lipolysis.

The glycerol and fatty acids that result from lipolysis are catabolized via different pathways (Figure 25.14). Glycerol is converted by many cells of the body to glyceraldehyde 3-phosphate, one of the compounds also formed during the catabolism of glucose. If ATP supply in a cell is high, glyceraldehyde 3-phosphate is converted into glucose, an example of gluconeogenesis. If ATP supply in a cell is low, glyceraldehyde 3-phosphate enters the catabolic pathway to pyruvic acid.

Fatty acids are catabolized differently than glycerol and yield more ATP. The first stage in fatty acid catabolism is a series of reactions, collectively called beta oxidation, that occurs in the matrix of mitochondria. Enzymes remove two carbon atoms at a time from the long chain of carbon atoms composing a fatty acid and attach the resulting two-carbon fragment to coenzyme A, forming acetyl CoA. Then, acetyl CoA enters the Krebs cycle (Figure 25.14). A 16-carbon fatty acid such as palmitic acid can yield as many as 129 ATPs upon its complete oxidation via beta oxidation, the Krebs cycle, and the electron transport chain.

As part of normal fatty acid catabolism, hepatocytes can take two acetyl CoA molecules at a time and condense them to form acetoacetic acid. This reaction liberates the bulky CoA portion, which cannot diffuse out of cells. Some acetoacetic acid is con-

What types of cells can carry out lipogenesis, beta oxidation, and lipolysis? What type of cell can carry out ketogenesis?
verted into **beta-hydroxybutyric acid** and **acetone**. The formation of these three substances, collectively known as **ketone bodies**, is called **ketogenesis** (Figure 25.14). Because ketone bodies freely diffuse through plasma membranes, they leave hepatocytes and enter the bloodstream.

Other cells take up acetoacetic acid and attach its four carbons to two coenzyme A molecules to form two acetyl CoA molecules, which can then enter the Krebs cycle for oxidation. Heart muscle and the cortex (outer part) of the kidneys use acetoacetic acid in preference to glucose for generating ATP. Hepatocytes, which make acetoacetic acid, cannot use it for ATP production because they lack the enzyme that transfers acetoacetic acid back to coenzyme A.

**Lipid Anabolism: Lipogenesis**

Liver cells and adipose cells can synthesize lipids from glucose or amino acids through **lipogenesis** (Figure 25.14), which is stimulated by insulin. Lipogenesis occurs when individuals consume more calories than are needed to satisfy their ATP needs. Excess dietary carbohydrates, proteins, and fats all have the same fate—they are converted into triglycerides. Certain amino acids can undergo the following reactions: amino acids → acetyl CoA → fatty acids → triglycerides. The use of glucose to form lipids takes place via two pathways: (1) glucose → glyceraldehyde 3-phosphate → glycerol and (2) glucose → glyceraldehyde 3-phosphate → acetyl CoA → fatty acids. The resulting glycerol and fatty acids can undergo anabolic reactions to become stored triglycerides, or they can go through a series of anabolic reactions to produce other lipids such as lipoproteins, phospholipids, and cholesterol.

### CLINICAL CONNECTION Ketosis

The level of ketone bodies in the blood normally is very low because other tissues use them for ATP production as fast as they are generated from the breakdown of fatty acids in the liver. During periods of excessive beta oxidation, however, the production of ketone bodies exceeds their uptake and use by body cells. This might occur after a meal rich in triglycerides, or during fasting or starvation, because few carbohydrates are available for catabolism. Excessive beta oxidation may also occur in poorly controlled or untreated diabetes mellitus for two reasons: (1) Because adequate glucose cannot get into cells, triglycerides are used for ATP production, and (2) because insulin normally inhibits lipolysis, a lack of insulin accelerates the pace of lipolysis. When the concentration of ketone bodies in the blood rises above normal—a condition called ketosis—the ketone bodies, most of which are acids, must be buffered. If too many accumulate, they decrease the concentration of buffers, such as bicarbonate ions, and blood pH falls. Extreme or prolonged ketosis can lead to **acidosis** (ketoacidosis), an abnormally low blood pH. The decreased blood pH in turn causes depression of the central nervous system, which can result in disorientation, coma, and even death if the condition is not treated. When a diabetic becomes seriously insulin-deficient, one of the telltale signs is the sweet smell on the breath from the ketone body acetone.

15. Where are triglycerides stored in the body?
16. Explain the principal events of the catabolism of glycerol and fatty acids.
17. What are ketone bodies? What is ketosis?
18. Define lipogenesis and explain its importance.

**PROTEIN METABOLISM**

**OBJECTIVE**

- Describe the fate, metabolism, and functions of proteins.

During digestion, proteins are broken down into amino acids. Unlike carbohydrates and triglycerides, which are stored, proteins are not warehoused for future use. Instead, amino acids are either oxidized to produce ATP or used to synthesize new proteins for body growth and repair. Excess dietary amino acids are not excreted in the urine or feces but instead are converted into glucose (gluconeogenesis) or triglycerides (lipogenesis).

**The Fate of Proteins**

The active transport of amino acids into body cells is stimulated by insulinlike growth factors (IGFs) and insulin. Almost immediately after digestion, amino acids are reassembled into proteins. Many proteins function as enzymes; others are involved in transportation (hemoglobin) or serve as antibodies, clotting chemicals (fibrinogen), hormones (insulin), or contractile elements in muscle fibers (actin and myosin). Several proteins serve as structural components of the body (collagen, elastin, and keratin). The various functions of proteins in the body may be reviewed in Table 2.8 on page 50.

**Protein Catabolism**

A certain amount of protein catabolism occurs in the body each day, stimulated mainly by cortisol from the adrenal cortex. Proteins from worn-out cells (such as red blood cells) are broken down into amino acids. Some amino acids are converted into other amino acids, peptide bonds are re-formed, and new proteins are synthesized as part of the recycling process. Hepatocytes convert some amino acids to fatty acids, ketone bodies, or glucose. Cells throughout the body oxidize a small amount of amino acids to generate ATP via the Krebs cycle and the electron transport chain. However, before amino acids can be oxidized, they must first be converted to molecules that are part of the Krebs cycle or can enter the Krebs cycle, such as acetyl CoA (Figure 25.15). Before amino acids can enter the Krebs cycle, their amino group (NH₂) must first be removed—a process called **deamination** (dē-am′-i-NÄ-shun). Deamination occurs...
in hepatocytes and produces ammonia (NH₃). The liver cells then convert the highly toxic ammonia to urea, a relatively harmless substance that is excreted in the urine. The conversion of amino acids into glucose (gluconeogenesis) may be reviewed in Figure 25.12; the conversion of amino acids into fatty acids (lipogenesis) or ketone bodies (ketogenesis) is shown in Figure 25.14.

**Question:** What group is removed from an amino acid before it can enter the Krebs cycle, and what is this process called?

**Protein Anabolism**

Protein anabolism, the formation of peptide bonds between amino acids to produce new proteins, is carried out on the ribosomes of almost every cell in the body, directed by the cells’ DNA and RNA (see Figure 3.29 on page 92). Insulinlike growth factors, thyroid hormones (T₃ and T₄), insulin, estrogen, and
testosterone stimulate protein synthesis. Because proteins are a main component of most cell structures, adequate dietary protein is especially essential during the growth years, during pregnancy, and when tissue has been damaged by disease or injury. Once dietary intake of protein is adequate, eating more protein will not increase bone or muscle mass; only a regular program of forceful, weight-bearing muscular activity accomplishes that goal.

Of the 20 amino acids in the human body, 10 are essential amino acids: They must be present in the diet because they cannot be synthesized in the body in adequate amounts. It is essential to include them in your diet. Humans are unable to synthesize eight amino acids (isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine) and synthesize two others (arginine and histidine) in inadequate amounts, especially in childhood. A complete protein contains sufficient amounts of all essential amino acids. Beef, fish, poultry, eggs, and milk are examples of foods that contain complete proteins. An incomplete protein does not contain all essential amino acids. Examples of incomplete proteins are leafy green vegetables, legumes (beans and peas), and grains. Nonessential amino acids can be synthesized by body cells. They are formed by transamination, the transfer of an amino group from an amino acid to pyruvic acid or to an acid in the Krebs cycle. Once the appropriate essential and nonessential amino acids are present in cells, protein synthesis occurs rapidly.

**Phenylketonuria**

Phenylketonuria (fen-’il-ké-tó-NOO-re-a) or PKU is a genetic error of protein metabolism characterized by elevated blood levels of the amino acid phenylalanine. Most children with PKU have a mutation in the gene that codes for the enzyme phenylalanine hydroxylase, the enzyme needed to convert phenylalanine into the amino acid tyrosine, which can enter the Krebs cycle (Figure 25.15). Because the enzyme is deficient, phenylalanine cannot be metabolized, and what is not used in protein synthesis builds up in the blood. If untreated, the disorder causes vomiting, rashes, seizures, growth deficiency, and severe mental retardation. Newborns are screened for PKU, and mental retardation can be prevented by restricting the affected child to a diet that supplies only the amount of phenylalanine needed for growth, although learning disabilities may still ensue. Because the artificial sweetener aspartame (NutraSweet) contains phenylalanine, its consumption must be restricted in children with PKU.

**Checkpoint**

19. What is deamination and why does it occur?
20. What are the possible fates of the amino acids from protein catabolism?
21. How are essential and nonessential amino acids different?

**The Role of Glucose 6-Phosphate**

Shortly after glucose enters a body cell, a kinase converts it to glucose 6-phosphate. Four possible fates await glucose 6-phosphate (see Figure 25.16):

1. **Synthesis of glycogen.** When glucose is abundant in the bloodstream, as it is just after a meal, a large amount of glucose 6-phosphate is used to synthesize glycogen, the storage form of carbohydrate in animals. Subsequent breakdown of glycogen into glucose 6-phosphate occurs through a slightly different series of reactions. Synthesis and breakdown of glycogen occur mainly in skeletal muscle fibers and hepatocytes.

2. **Release of glucose into the bloodstream.** If the enzyme glucose 6-phosphatase is present and active, glucose 6-phosphate can be dephosphorylated to glucose. Once glucose is released from the phosphate group, it can leave the cell and enter the bloodstream. Hepatocytes are the main cells that can provide glucose to the bloodstream in this way.

3. **Synthesis of nucleic acids.** Glucose 6-phosphate is the precursor used by cells throughout the body to make ribose 5-phosphate, a 5-carbon sugar that is needed for synthesis of RNA (ribonucleic acid) and DNA (deoxyribonucleic acid). The same sequence of reactions also produces NADPH. This molecule is a hydrogen and electron donor in certain reduction reactions, such as synthesis of fatty acids and steroid hormones.

4. **Glycolysis.** Some ATP is produced anaerobically via glycolysis, in which glucose 6-phosphate is converted to pyruvic acid, another key molecule in metabolism. Most body cells carry out glycolysis.

**The Role of Pyruvic Acid**

Each 6-carbon molecule of glucose that undergoes glycolysis yields two 3-carbon molecules of pyruvic acid. This molecule, like glucose 6-phosphate, stands at a metabolic crossroads:
Given enough oxygen, the aerobic (oxygen-consuming) reactions of cellular respiration can proceed; if oxygen is in short supply, anaerobic reactions can occur (Figure 25.16):

5 Production of lactic acid. When oxygen is in short supply in a tissue, as in actively contracting skeletal or cardiac muscle, some pyruvic acid is changed to lactic acid. The lactic acid then diffuses into the bloodstream and is taken up by hepatocytes, which eventually convert it back to pyruvic acid.

6 Production of alanine. Carbohydrate and protein metabolism are linked by pyruvic acid. Through transamination, an amino group (NH₃) can either be added to pyruvic acid (a carbohydrate) to produce the amino acid alanine, or be removed from alanine to generate pyruvic acid.

7 Gluconeogenesis. Pyruvic acid and certain amino acids also can be converted to oxaloacetic acid, one of the Krebs cycle intermediates, which in turn can be used to form glucose 6-phosphate. This sequence of gluconeogenesis reactions bypasses certain one-way reactions of glycolysis.

8 The Role of Acetyl Coenzyme A
   When the ATP level in a cell is low but oxygen is plentiful, most pyruvic acid streams toward ATP-producing reactions—the Krebs cycle and electron transport chain—via conversion to acetyl coenzyme A.

9 Entry into the Krebs cycle. Acetyl CoA is the vehicle for 2-carbon acetyl groups to enter the Krebs cycle. Oxidative Krebs cycle reactions convert acetyl CoA to CO₂ and produce reduced coenzymes (NADH and FADH₂) that transfer electrons into the electron transport chain. Oxidative reactions in the electron transport chain in turn generate ATP. Most fuel molecules that will be oxidized to generate ATP—glucose, fatty acids, and ketone bodies—are first converted to acetyl CoA.

10 Synthesis of lipids. Acetyl CoA also can be used for synthesis of certain lipids, including fatty acids, ketone bodies, and cholesterol. Because pyruvic acid can be converted to acetyl CoA, carbohydrates can be turned into triglycerides; this metabolic pathway stores some excess carbohydrate calories.
as fat. Mammals, including humans, cannot reconvert acetyl CoA to pyruvic acid, however, so fatty acids cannot be used to generate glucose or other carbohydrate molecules.

Table 25.2 summarizes carbohydrate, lipid, and protein metabolism.

**CHECKPOINT**
22. What are the possible fates of glucose 6-phosphate, pyruvic acid, and acetyl coenzyme A in a cell?

### METABOLIC ADAPTATIONS

**OBJECTIVE**
- Compare metabolism during the absorptive and postabsorptive states.

Regulation of metabolic reactions depends both on the chemical environment within body cells, such as the levels of ATP and oxygen, and on signals from the nervous and endocrine systems. Some aspects of metabolism depend on how much time has passed since the last meal. During the **absorptive state**, ingested nutrients are entering the bloodstream, and glucose is readily available for ATP production. During the **postabsorptive state**, absorption of nutrients from the GI tract is complete, and energy needs must be met by fuels already in the body. A typical meal requires about 4 hours for complete absorption; given three meals a day, the absorptive state exists for about 12 hours each day. Assuming no between-meal snacks, the other 12 hours—typically late morning, late afternoon, and most of the night—are spent in the postabsorptive state.

Because the nervous system and red blood cells continue to depend on glucose for ATP production during the postabsorptive state, maintaining a steady blood glucose level is critical during this period. Hormones are the major regulators of metabolism in each state. The effects of insulin dominate in the absorptive state; several other hormones regulate metabolism in the postabsorptive state. During fasting and starvation, many body cells turn to ketone bodies for ATP production, as noted in the Clinical Connection on page 993.

### Metabolism During the Absorptive State

Soon after a meal, nutrients start to enter the blood. Recall that ingested food reaches the bloodstream mainly as glucose, amino acids, and fats. Glucose, the primary energy source, is converted to glycogen in the liver and muscles for storage or used to generate ATP directly. Amino acids are converted to glucose or fatty acids. Fats are broken down into glycerol and fatty acids, which can be used for energy or stored as triglycerides.

Acids, and triglycerides (in chylomicrons). Two metabolic hallmarks of the absorptive state are the oxidation of glucose for ATP production, which occurs in most body cells, and the storage of excess fuel molecules for future between-meal use, which occurs mainly in hepatocytes, adipocytes, and skeletal muscle fibers.

**Absorptive State Reactions**
The following reactions dominate during the absorptive state (Figure 25.17):

1. About 50% of the glucose absorbed from a typical meal is oxidized by cells throughout the body to produce ATP via glycolysis, the Krebs cycle, and the electron transport chain.

2. Most glucose that enters hepatocytes is converted to glycogen. Small amounts may be used for synthesis of fatty acids and glyceroldehyde 3-phosphate.

3. Some fatty acids and triglycerides synthesized in the liver remain there, but hepatocytes package most into VLDLs, which carry lipids to adipose tissue for storage.

4. Adipocytes also take up glucose not picked up by the liver and convert it into triglycerides for storage. Overall, about 40% of the glucose absorbed from a meal is converted to triglycerides, and about 10% is stored as glycogen in skeletal muscles and hepatocytes.

5. Most dietary lipids (mainly triglycerides and fatty acids) are stored in adipose tissue; only a small portion is used for syn-

**Figure 25.17 Principal metabolic pathways during the absorptive state.**
During the absorptive state, most body cells produce ATP by oxidizing glucose to CO$_2$ and H$_2$O.

? Are the reactions shown in this figure mainly anabolic or catabolic?
thesis reactions. Adipocytes obtain the lipids from chylomicrons, from VLDLs, and from their own synthesis reactions.

Many absorbed amino acids that enter hepatocytes are deaminated to keto acids, which can either enter the Krebs cycle for ATP production or be used to synthesize glucose or fatty acids.

Some amino acids that enter hepatocytes are used to synthesize proteins (for example, plasma proteins).

Amino acids not taken up by hepatocytes are used in other body cells (such as muscle cells) for synthesis of proteins or regulatory chemicals such as hormones or enzymes.

**Regulation of Metabolism During the Absorptive State**

Soon after a meal, glucose-dependent insulinotropic peptide (GIP), plus the rising blood levels of glucose and certain amino acids, stimulate pancreatic beta cells to release insulin. In general, insulin increases the activity of enzymes needed for anabolism and the synthesis of storage molecules; at the same time it decreases the activity of enzymes needed for catabolic or breakdown reactions. Insulin promotes the entry of glucose and amino acids into cells of many tissues, and it stimulates the phosphorylation of glucose in hepatocytes and the conversion of glucose 6-phosphate to glycogen in both liver and muscle cells. In liver and adipose tissue, insulin enhances the synthesis of triglycerides, and in cells throughout the body insulin stimulates protein synthesis. (See page 671 to review the effects of insulin.) Insulin-like growth factors and the thyroid hormones (T3 and T4) also stimulate protein synthesis. Table 25.3 summarizes the hormonal regulation of metabolism in the absorptive state.

**Metabolism During the Postabsorptive State**

About 4 hours after the last meal, absorption of nutrients from the small intestine is nearly complete, and blood glucose level starts to fall because glucose continues to leave the bloodstream and enter body cells while none is being absorbed from the GI tract. Thus, the main metabolic challenge during the postabsorptive state is to maintain the normal blood glucose level of 70–110 mg/100 mL (3.9–6.1 mmol/liter). Homeostasis of blood glucose concentration is especially important for the nervous system and for red blood cells for the following reasons:

- The dominant fuel molecule for ATP production in the nervous system is glucose, because fatty acids are unable to pass the blood–brain barrier.
- Red blood cells derive all their ATP from glycolysis of glucose because they have no mitochondria, so the Krebs cycle and the electron transport chain are not available to them.

**Postabsorptive State Reactions**

During the postabsorptive state, both glucose production and glucose conservation help maintain blood glucose level:

*Facilitated diffusion of glucose into hepatocytes (liver cells) and neurons is always “turned on” and does not require insulin.

Hepatocytes produce glucose molecules and export them into the blood, and other body cells switch from glucose to alternative fuels for ATP production to conserve scarce glucose. The major reactions of the postabsorptive state that produce glucose are the following (Figure 25.18):

1. **Breakdown of liver glycogen.** During fasting, a major source of blood glucose is liver glycogen, which can provide about a 4-hour supply of glucose. Liver glycogen is continually being formed and broken down as needed.

2. **Lipolysis.** Glycerol, produced by breakdown of triglycerides in adipose tissue, is also used to form glucose.

3. **Gluconeogenesis using lactic acid.** During exercise, skeletal muscle tissue breaks down stored glycogen (see step 9) and produces some ATP anaerobically via glycolysis. Some of the pyruvic acid that results is converted to acetyl CoA, and some is converted to lactic acid, which diffuses into the blood. In the liver, lactic acid can be used for gluconeogenesis, and the resulting glucose is released into the blood.

4. **Gluconeogenesis using amino acids.** Modest breakdown of proteins in skeletal muscle and other tissues releases large amounts of amino acids, which then can be converted to glucose by gluconeogenesis in the liver.

Despite all of these ways the body produces glucose, blood glucose level cannot be maintained for very long without further metabolic changes. Thus, a major adjustment must be made during the postabsorptive state to produce ATP while conserving...
glucose. The following reactions produce ATP without using glucose:

5 Oxidation of fatty acids. The fatty acids released by lipolysis of triglycerides cannot be used for glucose production because acetyl CoA cannot be readily converted to pyruvic acid. But most cells can oxidize the fatty acids directly, feed them into the Krebs cycle as acetyl CoA, and produce ATP through the electron transport chain.

6 Oxidation of lactic acid. Cardiac muscle can produce ATP aerobically from lactic acid.

7 Oxidation of amino acids. In hepatocytes, amino acids may be oxidized directly to produce ATP.

8 Oxidation of ketone bodies. Hepatocytes also convert fatty acids to ketone bodies, which can be used by the heart, kidneys, and other tissues for ATP production.

9 Breakdown of muscle glycogen. Skeletal muscle cells break down glycogen to glucose 6-phosphate, which undergoes glycolysis and provides ATP for muscle contraction.

Regulation of Metabolism During the Postabsorptive State

Both hormones and the sympathetic division of the autonomic nervous system (ANS) regulate metabolism during the postabsorptive state. The hormones that regulate postabsorptive state metabolism sometimes are called anti-insulin hormones because they counter the effects of insulin during the absorptive state. As blood glucose level declines, the secretion of insulin falls and the release of anti-insulin hormones rises.

When blood glucose concentration starts to drop, the pancreatic alpha cells release glucagon at a faster rate, and the beta cells secrete insulin more slowly. The primary target tissue of glucagon is the liver; the major effect is increased release of glucose into the bloodstream due to gluconeogenesis and glycogenolysis.

Low blood glucose also activates the sympathetic branch of the ANS. Glucose-sensitive neurons in the hypothalamus detect low blood glucose and increase sympathetic output. As a result, sympathetic nerve endings release the neurotransmitter norepinephrine,
The term fasting means going without food for many hours or a few days; starvation implies weeks or months of food deprivation or inadequate food intake. People can survive without food for two months or more if they drink enough water to prevent dehydration. Although glycogen stores are depleted within a few hours of beginning a fast, catabolism of stored triglycerides and structural proteins can provide energy for several weeks. The amount of adipose tissue the body contains determines the lifespan possible without food.

During fasting and starvation, nervous tissue and RBCs continue to use glucose for ATP production. There is a ready supply of amino acids for gluconeogenesis because lowered insulin and increased cortisol levels slow the pace of protein synthesis and promote protein catabolism. Most cells in the body, especially skeletal muscle cells because of their high protein content, can spare a fair amount of protein before their performance is adversely affected. During the first few days of fasting, protein catabolism outpaces protein synthesis by about 75 grams daily as some of the “old” amino acids are being deaminated and used for gluconeogenesis and “new” (that is, dietary) amino acids are lacking.

By the second day of a fast, blood glucose level has stabilized at about 65 mg/100 mL (3.6 mmol/liter); at the same time the level of fatty acids in plasma has risen fourfold. Lipolysis of triglycerides in adipose tissue releases glycerol, which is used for gluconeogenesis, and fatty acids. The fatty acids diffuse into muscle fibers and other body cells, where they are used to produce acetyl-CoA, which enters the Krebs cycle. ATP then is synthesized as oxidation proceeds via the Krebs cycle and the electron transport chain.

The most dramatic metabolic change that occurs with fasting and starvation is the increase in the formation of ketone bodies by hepatocytes. During fasting, only small amounts of glucose undergo glycolysis to pyruvic acid, which in turn can be converted to oxaloacetic acid. Acetyl-CoA enters the Krebs cycle by combining with oxaloacetic acid (see Figure 25.16); when oxaloacetic acid is scarce due to fasting, only some of the available acetyl-CoA can enter the Krebs cycle. Surplus acetyl-CoA is used for ketogenesis, mainly in hepatocytes. Ketone body production thus increases as catabolism of fatty acids rises. Lipid-soluble ketone bodies can diffuse through plasma membranes and across the blood–brain barrier and be used as an alternative fuel for ATP production, especially by cardiac and skeletal muscle fibers and neurons. Normally, only a trace of ketone bodies (0.01 mmol/liter) are present in the blood, so they are a negligible fuel source. After two days of fasting, however, the level of ketones is 100–300 times higher and supplies roughly a third of the brain’s fuel for ATP production. By 40 days of starvation, ketones provide up to two-thirds of the brain’s energy needs. The presence of ketones actually reduces the use of glucose for ATP production, which in turn decreases the demand for gluconeogenesis and slows the catabolism of muscle proteins later in starvation to about 20 grams daily.

### CHECKPOINT

23. What are the roles of insulin, glucagon, epinephrine, insulin-like growth factors, thyroxine, cortisol, estrogen, and testosterone in regulation of metabolism?

24. Why is ketogenesis more significant during fasting or starvation than during normal absorptive and postabsorptive states?

### HEAT AND ENERGY BALANCE

#### OBJECTIVES

- Define basal metabolic rate (BMR), and explain several factors that affect it.
- Describe the factors that influence body heat production.
- Explain how normal body temperature is maintained by negative feedback loops involving the hypothalamic thermostat.

Your body produces more or less heat depending on the rates of its metabolic reactions. Because homeostasis of body temperature can be maintained only if the rate of heat loss from the body
equals the rate of heat production by metabolism, it is important to understand the ways in which heat can be lost, gained, or conserved. Heat is a form of energy that can be measured as temperature and expressed in units called calories. A calorie (cal) is defined as the amount of heat required to raise the temperature of 1 gram of water 1°C. Because the calorie is a relatively small unit, the kilocalorie (kcal) or Calorie (Cal) (always spelled with an uppercase C) is often used to measure the body’s metabolic rate and to express the energy content of foods. A kilocalorie equals 1000 calories. Thus, when we say that a particular food item contains 500 Calories, we are actually referring to kilocalories.

Metabolic Rate

The overall rate at which metabolic reactions use energy is termed the metabolic rate. As you have already learned, some of the energy is used to produce ATP, and some is released as heat. Because many factors affect metabolic rate, it is measured under standard conditions, with the body in a quiet, resting, and fasting condition called the basal state. The measurement obtained under these conditions is the basal metabolic rate (BMR). The most common way to determine BMR is by measuring the amount of oxygen used per kilocalorie of food metabolized. When the body uses 1 liter of oxygen to oxidize a typical dietary mixture of triglycerides, carbohydrates, and proteins, about 4.8 Cal of energy is released. BMR is 1200–1800 Cal/day in adults, or about 24 Cal/kg of body mass in adult males and 22 Cal/kg in adult females. The added calories needed to support daily activities, such as digestion and walking, range from 500 Cal for a small, relatively sedentary person to over 3000 Cal for a person in training for Olympic-level competitions or mountain climbing.

Body Temperature Homeostasis

Despite wide fluctuations in environmental temperature, homeostatic mechanisms can maintain a normal range for internal body temperature. If the rate of body heat production equals the rate of heat loss, the body maintains a constant core temperature near 37°C (98.6°F). Core temperature is the temperature in body structures deep to the skin and subcutaneous layer. Shell temperature is the temperature near the body surface—in the skin and subcutaneous layer. Depending on the environmental temperature, shell temperature is 1–6°C lower than core temperature. A core temperature that is too high kills by denaturing body proteins; a core temperature that is too low causes cardiac arrhythmias that result in death.

Heat Production

The production of body heat is proportional to metabolic rate. Several factors affect the metabolic rate and thus the rate of heat production:

- **Exercise.** During strenuous exercise, the metabolic rate may increase to as much as 15 times the basal rate. In well-trained athletes, the rate may increase up to 20 times.

- **Hormones.** Thyroid hormones (thyroxine and triiodothyronine) are the main regulators of BMR; BMR increases as the blood levels of thyroid hormones rise. The response to changing levels of thyroid hormones is slow, however, taking several days to appear. Thyroid hormones increase BMR in part by stimulating aerobic cellular respiration. As cells use more oxygen to produce ATP, more heat is given off, and body temperature rises. Other hormones have minor effects on BMR. Testosterone, insulin, and human growth hormone can increase the metabolic rate by 5–15%.

- **Nervous system.** During exercise or in a stressful situation, the sympathetic division of the autonomic nervous system is stimulated. Its postganglionic neurons release norepinephrine (NE), and it also stimulates release of the hormones epinephrine and norepinephrine by the adrenal medulla. Both epinephrine and norepinephrine increase the metabolic rate of body cells.

- **Body temperature.** The higher the body temperature, the higher the metabolic rate. Each 1°C rise in core temperature increases the rate of biochemical reactions by about 10%. As a result, metabolic rate may be increased substantially during a fever.

- **Ingestion of food.** The ingestion of food raises the metabolic rate 10–20% due to the energy “costs” of digesting, absorbing, and storing nutrients. This effect, food-induced thermogenesis, is greatest after eating a high-protein meal and is less after eating carbohydrates and lipids.

- **Age.** The metabolic rate of a child, in relation to its size, is about double that of an elderly person due to the high rates of reactions related to growth.

- **Other factors.** Other factors that affect metabolic rate are gender (lower in females, except during pregnancy and lactation), climate (lower in tropical regions), sleep (lower), and malnutrition (lower).

Mechanisms of Heat Transfer

Maintaining normal body temperature depends on the ability to lose heat to the environment at the same rate as it is produced by metabolic reactions. Heat can be transferred from the body to its surroundings in four ways: via conduction, convection, radiation, and evaporation.

1. **Conduction** is the heat exchange that occurs between molecules of two materials that are in direct contact with each other. At rest, about 3% of body heat is lost via conduction to solid materials in contact with the body, such as a chair, clothing, and jewelry. Heat can also be gained via conduction—for example, while soaking in a hot tub. Because water conducts heat 20 times more effectively than air, heat loss or heat gain via conduction is much greater when the body is submerged in cold or hot water.

2. **Convection** is the transfer of heat by the movement of a fluid (a gas or a liquid) between areas of different temperature.
The contact of air or water with your body results in heat transfer by both conduction and convection. When cool air makes contact with the body, it becomes warmed and therefore less dense and is carried away by convection currents created as less dense air rises. The faster the air moves—for example, by a breeze or a fan—the faster the rate of convection. At rest, about 15% of body heat is lost to the air via conduction and convection.

3. Radiation is the transfer of heat in the form of infrared rays between a warmer object and a cooler one without physical contact. Your body loses heat by radiating more infrared waves than it absorbs from cooler objects. If surrounding objects are warmer than you are, you absorb more heat than you lose by radiation.

In a room at 21°C (70°F), about 60% of heat loss occurs via radiation in a resting person.

4. Evaporation is the conversion of a liquid to a vapor. Every milliliter of evaporating water takes with it a great deal of heat—about 0.58 Cal/mL. Under typical resting conditions, about 22% of heat loss occurs through evaporation of about 700 mL of water per day—300 mL in exhaled air and 400 mL from the skin surface. Because we are not normally aware of this water loss through the skin and mucous membranes of the mouth and respiratory system, it is termed insensible water loss. The rate of evaporation is inversely related to relative humidity, the ratio of the actual amount of moisture in the air to the maximum amount it can hold at a given temperature. The higher the relative humidity, the lower the rate of evaporation. At 100% humidity, heat is gained via condensation of water on the skin surface as fast as heat is lost via evaporation. Evaporation provides the main defense against overheating during exercise. Under extreme conditions, a maximum of about 3 liters of sweat can be produced each hour, removing more than 1700 Calories of heat if all of it evaporates. (Note: Sweat that drips off the body rather than evaporating removes very little heat.)

Hypothalamic Thermostat

The control center that functions as the body’s thermostat is a group of neurons in the anterior part of the hypothalamus, the preoptic area. This area receives impulses from thermoreceptors in the skin and mucous membranes and in the hypothalamus. Neurons of the preoptic area generate nerve impulses at a higher frequency when blood temperature increases, and at a lower frequency when blood temperature decreases.

Nerve impulses from the preoptic area propagate to two other parts of the hypothalamus known as the heat-losing center and the heat-promoting center, which, when stimulated by the preoptic area, set into operation a series of responses that lower body temperature and raise body temperature, respectively.

Thermoregulation

If core temperature declines, mechanisms that help conserve heat and increase heat production act via several negative feedback loops to raise the body temperature to normal (Figure 25.19). Thermoreceptors in the skin and hypothalamus send nerve impulses to the preoptic area and the heat-promoting center in the hypothalamus, and to hypothalamic neurosecretory cells that produce thyrotropin-releasing hormone (TRH). In response, the hypothalamus discharges nerve impulses and secretes TRH, which in turn stimulates thyrotrophs in the anterior pituitary gland to release thyroid-stimulating hormone (TSH). Nerve impulses from the hypothalamus and TSH then activate several effectors.

Each effector responds in a way that helps increase core temperature to the normal value:

- Nerve impulses from the heat-promoting center stimulate sympathetic nerves that cause blood vessels of the skin to constrict. Vasoconstriction decreases the flow of warm blood, and thus the transfer of heat, from the internal organs to the skin. Slowing the rate of heat loss allows the internal body temperature to increase as metabolic reactions continue to produce heat.

- Nerve impulses in sympathetic nerves leading to the adrenal medulla stimulate the release of epinephrine and norepinephrine into the blood. The hormones in turn bring about an increase in cellular metabolism, which increases heat production.

- The heat-promoting center stimulates parts of the brain that increase muscle tone and hence heat production. As muscle tone increases in one muscle (the agonist), the small contractions stretch muscle spindles in its antagonist, initiating a stretch reflex. The resulting contraction in the antagonist stretches muscle spindles in the agonist, and it too develops a stretch reflex. This repetitive cycle—called shivering—greatly increases the rate of heat production. During maximal shivering, body heat production can rise to about four times the basal rate in just a few minutes.

- The thyroid gland responds to TSH by releasing more thyroid hormones into the blood. As increased levels of thyroid hormones slowly increase the metabolic rate, body temperature rises.

If core body temperature rises above normal, a negative feedback loop opposite to the one depicted in Figure 25.19 goes into action. The higher temperature of the blood stimulates thermoreceptors that send nerve impulses to the preoptic area, which in turn stimulate the heat-losing center and inhibit the heat-promoting center. Nerve impulses from the heat-losing center cause dilation of blood vessels in the skin. The skin becomes warm, and the excess heat is lost to the environment via radiation and conduction as an increased volume of blood flows from the warmer core of the body into the cooler skin. At the same time, metabolic rate decreases, and shivering does not occur. The high temperature of the blood stimulates sweat glands of the skin via hypothalamic activation of sympathetic nerves. As the water in perspiration evaporates from the surface of the skin, the skin is cooled. All these responses counteract heat-promoting effects and help return body temperature to normal.
Negative feedback mechanisms that conserve heat and increase heat production.

Core temperature is the temperature in body structures deep to the skin and subcutaneous layer; shell temperature is the temperature near the body surface.

- Vasoconstriction decreases heat loss through the skin.
- Adrenal medulla releases hormones that increase cellular metabolism.
- Skeletal muscles contract in a repetitive cycle called shivering.
- Thyroid gland releases thyroid hormones, which increase metabolic rate.

Some stimulus disrupts homeostasis by decreasing body temperature. Receptors, such as thermoreceptors in skin and hypothalamus, detect the temperature change. Control centers, including the preoptic area, heat promoting center, and neurosecretory cells in hypothalamus and thyrotropes in anterior pituitary gland, respond by stimulating effectors. Effectors include the adrenal medulla and skeletal muscles. Nerve impulses to the control centers and TSH (thyroid-stimulating hormone) from the anterior pituitary gland return to homeostasis when response brings body temperature back to normal.

What factors can increase metabolic rate and thus increase the rate of heat production?

**CLINICAL CONNECTION** Hypothermia

Hypothermia is a lowering of core body temperature to 35°C (95°F) or below. Causes of hypothermia include an overwhelming cold stress (immersion in icy water), metabolic diseases (hypoglycemia, adrenal insufficiency, or hypothyroidism), drugs (alcohol, antidepressants, sedatives, or tranquilizers), burns, and malnutrition. Hypothermia is characterized by the following as core body temperature falls: sensation of cold, shivering, confusion, vasoconstriction, muscle rigidity, bradycardia, acidosis, hypoventilation, hypotension, loss of spontaneous movement, coma, and death (usually caused by cardiac arrhythmias). Because the elderly have reduced metabolic protection against a cold environment coupled with a reduced perception of cold, they are at greater risk for developing hypothermia.
Energy Homeostasis and Regulation of Food Intake

Most mature animals and many men and women maintain **energy homeostasis**, the precise matching of energy intake (in food) to energy expenditure over time. When the energy content of food balances the energy used by all the cells of the body, body weight remains constant (unless there is a gain or loss of water). In many people, weight stability persists despite large day-to-day variations in activity and food intake. In the more affluent nations, however, a large fraction of the population is overweight. Easy access to tasty, high-calorie foods and a “couch-potato” lifestyle promote weight gain. Being overweight increases the risk of dying from a variety of cardiovascular and metabolic disorders, including hypertension, varicose veins, diabetes mellitus, arthritis, certain cancers, and gallbladder disease.

Energy intake depends only on the amount of food consumed (and absorbed), but three components contribute to total energy expenditure:

1. **The basal metabolic rate** accounts for about 60% of energy expenditure.
2. **Physical activity** typically adds 30–35% but can be lower in sedentary people. The energy expenditure is partly from voluntary exercise, such as walking, and partly from **nonexercise activity thermogenesis (NEAT)**, the energy costs for maintaining muscle tone, posture while sitting or standing, and involuntary fidgeting movements.
3. **Food-induced thermogenesis**, the heat produced while food is being digested, absorbed, and stored, represents 5–10% of total energy expenditure.

The major site of stored chemical energy in the body is adipose tissue. When energy use exceeds energy input, triglycerides in adipose tissue are catabolized to provide the extra energy, and when energy input exceeds energy expenditure, triglycerides are stored. Over time, the amount of stored triglycerides indicates the excess of energy intake over energy expenditure. Even small differences add up over time. A gain of 20 lb (9 kg) between ages 25 and 55 represents only a tiny imbalance, about 0.3% more energy intake in food than energy expenditure.

Clearly, negative feedback mechanisms are regulating both our energy intake and our energy expenditure. But no sensory receptors exist to monitor our weight or size. How, then, is food intake regulated? The answer to this question is incomplete, but important advances in understanding regulation of food intake have occurred in the past decade. It depends on many factors, including neural and endocrine signals, levels of certain nutrients in the blood, psychological elements such as stress or depression, signals from the GI tract and the special senses, and neural connections between the hypothalamus and other parts of the brain.

Within the hypothalamus are clusters of neurons that play key roles in regulating food intake. **Satiety** (sa-TI-é-té) is a feeling of fullness accompanied by lack of desire to eat. Two hypothalamic areas involved in regulation of food intake are the **arcuate nucleus** and the **paraventricular nucleus** (see Figure 14.10 on page 512). In 1994, the first experiments were reported on a mouse gene, named *obese*, that causes overeating and severe obesity in its mutated form. The product of this gene is the hormone **leptin**. In both mice and humans, leptin helps decrease **adiposity**, total body-fat mass. Leptin is synthesized and secreted by adipocytes in proportion to adiposity; as more triglycerides are stored, more leptin is secreted into the bloodstream. Leptin acts on the hypothalamus to inhibit circuits that stimulate eating while also activating circuits that increase energy expenditure. The hormone insulin has a similar, but smaller, effect. Both leptin and insulin are able to pass through the blood–brain barrier.

When leptin and insulin levels are low, neurons that extend from the arcuate nucleus to the paraventricular nucleus release a neurotransmitter called **neuropeptide Y** that stimulates food intake. Other neurons that extend between the arcuate and paraventricular nuclei release a neurotransmitter called **melanocortin**, which is similar to melanocyte-stimulating hormone (MSH). Leptin stimulates release of melanocortin, which acts to inhibit food intake. Although leptin, neuropeptide Y, and melanocortin are key signaling molecules for maintaining energy homeostasis, several other hormones and neurotransmitters also contribute. An understanding of the brain circuits involved is still far from complete. Other areas of the hypothalamus plus nuclei in the brain stem, limbic system, and cerebral cortex take part.

Achieving energy homeostasis requires regulation of energy intake. Most increases and decreases in food intake are due to changes in meal size rather than changes in number of meals. Many experiments have demonstrated the presence of satiety signals, chemical or neural changes that help terminate eating when “fullness” is attained. For example, an increase in blood glucose level, as occurs after a meal, decreases appetite. Several hormones, such as glucagon, cholecystokinin, estrogens, and epinephrine (acting via beta receptors) act to signal satiety and to increase energy expenditure. Distension of the GI tract, particularly the stomach and duodenum, also contributes to termination of food intake. Other hormones increase appetite and decrease energy expenditure. These include growth hormone–releasing hormone (GHRH), androgens, glucocorticoids, epinephrine (acting via alpha receptors), and progesterone.

---

**CLINICAL CONNECTION** Emotional Eating

In addition to keeping us alive, eating serves countless psychological, social, and cultural purposes. We eat to celebrate, punish, comfort, defy, and deny. Eating in response to emotional drives, such as feeling stressed, bored, or tired, is called **emotional eating**. Emotional eating is so common that, within limits, it is considered well within the range of normal behavior. Who hasn’t at one time or another headed for the refrigerator after a bad day? Problems arise when emotional eating becomes so excessive that it interferes with health. Physical health problems include obesity and associated disorders such as hypertension and heart disease. Psychological health problems include poor self-
25. Define a kilocalorie (kcal). How is the unit used? How does it relate to a calorie?

26. Distinguish between core temperature and shell temperature.

27. In what ways can a person lose heat to or gain heat from the surroundings? How is it possible for a person to lose heat on a sunny beach when the temperature is 40°C (104°F) and the humidity is 85%?

28. What does the term energy homeostasis mean?

29. How is food intake regulated?

NUTRITION

OBJECTIVES

• Describe how to select foods to maintain a healthy diet.
• Compare the sources, functions, and importance of minerals and vitamins in metabolism.

Nutrients are chemical substances in food that body cells use for growth, maintenance, and repair. The six main types of nutrients are water, carbohydrates, lipids, proteins, minerals, and vitamins. Water is the nutrient needed in the largest amount—about 2–3 liters per day. As the most abundant compound in the body, water provides the medium in which most metabolic reactions occur, and it also participates in some reactions (for example, hydrolysis reactions). The important roles of water in the body can be reviewed on pages 39–40. Three organic nutrients—carbohydrates, lipids, and proteins—provide the energy needed for metabolic reactions and serve as building blocks to make body structures. Some minerals and many vitamins are components of the enzyme systems that catalyze metabolic reactions. Essential nutrients are specific nutrient molecules that the body cannot make in sufficient quantity to meet its needs and thus must be obtained from the diet. Some amino acids, fatty acids, vitamins, and minerals are essential nutrients.

Next, we discuss some guidelines for healthy eating and the roles of minerals and vitamins in metabolism.

Guidelines for Healthy Eating

Each gram of protein or carbohydrate in food provides about 4 Calories; 1 gram of fat (lipids) provides about 9 Calories. We do not know with certainty what levels and types of carbohydrate, fat, and protein are optimal in the diet. Different populations around the world eat radically different diets that are adapted to their particular lifestyles. However, many experts recommend the following distribution of calories: 50–60% from carbohydrates, with less than 15% from simple sugars; less than 30% from fats (triglycerides are the main type of dietary fat), with no more than 10% as saturated fats; and about 12–15% from proteins.

Figure 25.20 MyPyramid.

MyPyramid is a new, personalized approach to making healthy food choices and maintaining regular physical activity.

What does the wider base of each band mean?
The guidelines for healthy eating are to:

- Eat a variety of foods.
- Maintain a healthy weight.
- Choose foods low in fat, saturated fat, and cholesterol.
- Eat plenty of vegetables, fruits, and grain products.
- Use sugars in moderation only.

In 2005, the United States Department of Agriculture (USDA) introduced a new food pyramid called MyPyramid, which represents a personalized approach to making healthy food choices and maintaining regular physical activity. By consulting a chart, it is possible to determine your calorie level based on your gender, age, and activity level. Once this is determined, you can choose the type and amount of food to be consumed.

If you carefully examine the MyPyramid in Figure 25.20 on page 1006 you will note that the six color bands represent the five basic food groups plus oils. Foods from all bands are needed each day. Also note that the overall size of the bands suggests the proportion of food a person should choose on a daily basis. The wider base of each band represents foods with little or no solid fats or added sugars; these foods should be selected more often. The narrower top of each band represents foods with more added sugars and solid fats, which should be selected less frequently. The person climbing the steps is a reminder of the need for daily physical activity.

As an example of how the MyPyramid works, let’s assume based upon consulting a chart that the calorie level of an 18-year-old moderately active female is 2000 Calories and that of an 18-year-old moderately active male is 2800 Calories. Accordingly, it is suggested that the following foods should be chosen in the following amounts:

<table>
<thead>
<tr>
<th>Calorie Level</th>
<th>2000</th>
<th>2800</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fruits</td>
<td>2 cups</td>
<td>2.5 cups</td>
</tr>
<tr>
<td>Vegetables</td>
<td>2.5 cups</td>
<td>3.5 cups</td>
</tr>
<tr>
<td>Grains</td>
<td>6 oz</td>
<td>10 oz</td>
</tr>
<tr>
<td>Meats and beans</td>
<td>5.5 oz</td>
<td>7 oz</td>
</tr>
<tr>
<td>Milk group</td>
<td>3 cups</td>
<td>3 cups</td>
</tr>
<tr>
<td>Oils</td>
<td>6 tsp</td>
<td>8 tsp</td>
</tr>
</tbody>
</table>

In addition, you should choose and prepare foods with little salt. In fact, sodium intake should be less than 2300 mg per day. If you choose to drink alcohol, it should be consumed in moderation (no more than 1 drink per day for women and 2 drinks per day for men). A drink is defined as 12 oz of regular beer, 5 oz of wine, or 1 1/2 oz of 80 proof distilled spirits.

**Minerals**

Minerals are inorganic elements that occur naturally in the Earth’s crust. In the body they appear in combination with one another, in combination with organic compounds, or as ions in solution. Minerals constitute about 4% of total body mass and are concentrated most heavily in the skeleton. Minerals with known functions in the body include calcium, phosphorus, potassium, sulfur, sodium, chloride, magnesium, iron, iodide, manganese, copper, cobalt, zinc, fluoride, selenium, and chromium. Table 25.5 describes the vital functions of these minerals. Note that the body generally uses the ions of the minerals rather than the non-ionized form. Some minerals, such as chlorine, are toxic or even fatal if ingested in the non-ionized form. Other minerals—aluminum, boron, silicon, and molybdenum—are present but their functions are unclear. Typical diets supply adequate amounts of potassium, sodium, chloride, and magnesium. Some attention must be paid to eating foods that provide enough calcium, phosphorus, iron, and iodide. Excess amounts of most minerals are excreted in the urine and feces.

Calcium and phosphorus form part of the matrix of bone. Because minerals do not form long-chain compounds, they are otherwise poor building materials. A major role of minerals is to help regulate enzymatic reactions. Calcium, iron, magnesium, and manganese are constituents of some coenzymes. Magnesium also serves as a catalyst for the conversion of ADP to ATP. Minerals such as sodium and phosphorus work in buffer systems, which help control the pH of body fluids. Sodium also helps regulate the osmosis of water and, along with other ions, is involved in the generation of nerve impulses.

**Vitamins**

Organic nutrients required in small amounts to maintain growth and normal metabolism are called vitamins. Unlike carbohydrates, lipids, or proteins, vitamins do not provide energy or serve as the body’s building materials. Most vitamins with known functions are coenzymes.

Most vitamins cannot be synthesized by the body and must be ingested in food. Other vitamins, such as vitamin K, are produced by bacteria in the GI tract and then absorbed. The body can assemble some vitamins if the raw materials, called provitamins, are provided. For example, vitamin A is produced by the body from the provitamin beta-carotene, a chemical present in yellow vegetables such as carrots and in dark green vegetables such as spinach. No single food contains all the required vitamins—one of the best reasons to eat a varied diet.

Vitamins are divided into two main groups: fat-soluble and water-soluble. The fat-soluble vitamins, vitamins A, D, E, and K, are absorbed along with other dietary lipids in the small intestine and packaged into chylomicrons. They cannot be absorbed in adequate quantity unless they are ingested with other lipids.
Fat-soluble vitamins may be stored in cells, particularly hepatocytes. The water-soluble vitamins, including several B vitamins and vitamin C, are dissolved in body fluids. Excess quantities of these vitamins are not stored but instead are excreted in the urine.

Besides their other functions, three vitamins—C, E, and beta-carotene (a provitamin)—are termed antioxidant vitamins because they inactivate oxygen free radicals. Recall that free radicals are highly reactive ions or molecules that carry an unpaired electron in their outermost electron shell (see Figure 2.3 on page 32). Free radicals damage cell membranes, DNA, and other cellular structures and contribute to the formation of artery-narrowing atherosclerotic plaques. Some free radicals arise naturally in the body, and others come from environmental hazards such as tobacco smoke and radiation. Antioxidant vitamins are thought to play a role in protecting against some kinds of cancer, reducing the buildup of atherosclerotic plaque, delaying some effects of aging, and decreasing the chance of cataract formation in the lens of the eyes. Table 25.6 on pages 1010–1011 lists the major vitamins, their sources, their functions, and related deficiency disorders.

**TABLE 25.5**

<table>
<thead>
<tr>
<th>MINERAL</th>
<th>COMMENTS</th>
<th>IMPORTANCE</th>
</tr>
</thead>
<tbody>
<tr>
<td>Calcium</td>
<td>Most abundant mineral in body. Appears in combination with phosphates. About 99% is stored in bone and teeth. Blood Ca(^2+) level is controlled by parathyroid hormone (PTH). Calcitriol promotes absorption of dietary calcium. Excess is excreted in feces and urine. Sources are milk, egg yolk, shellfish, and leafy green vegetables.</td>
<td>Formation of bones and teeth, blood clotting, normal muscle and nerve activity, endocytosis and exocytosis, cellular motility, chromosome movement during cell division, glycogen metabolism, and release of neurotransmitters and hormones.</td>
</tr>
<tr>
<td>Phosphorus</td>
<td>About 80% is found in bones and teeth as phosphate salts. Blood phosphate level is controlled by parathyroid hormone (PTH). Excess is excreted in urine; small amount is eliminated in feces. Sources are dairy products, meat, fish, poultry, and nuts.</td>
<td>Formation of bones and teeth. Phosphates (H(_2)PO(_4)^−, HPO(_4)^−, and PO(_4)^{3−}) constitute a major buffer system of blood. Plays important role in muscle contraction and nerve activity. Component of many enzymes. Involved in energy transfer (ATP). Component of DNA and RNA.</td>
</tr>
<tr>
<td>Potassium</td>
<td>Major cation (K(^+)) in intracellular fluid. Excess excreted in urine. Present in most foods (meats, fish, poultry, fruits, and nuts).</td>
<td>Needed for generation and conduction of action potentials in neurons and muscle fibers.</td>
</tr>
<tr>
<td>Sulfur</td>
<td>Component of many proteins (such as insulin and chondroitin sulfate), electron carriers in electron transport chain, and some vitamins (thiamine and biotin). Excreted in urine. Sources include beef, liver, lamb, fish, poultry, eggs, cheese, and beans.</td>
<td>As component of hormones and vitamins, regulates various body activities. Needed for ATP production by electron transport chain.</td>
</tr>
<tr>
<td>Sodium</td>
<td>Most abundant cation (Na(^+)) in extracellular fluids; some found in bones. Excreted in urine and perspiration. Normal intake of NaCl (table salt) supplies more than the required amounts.</td>
<td>Strongly affects distribution of water through osmosis. Part of bicarbonate buffer system. Functions in nerve and muscle action potential conduction.</td>
</tr>
<tr>
<td>Chloride</td>
<td>Major anion (Cl(^−)) in extracellular fluid. Excess excreted in urine. Sources include table salt (NaCl), soy sauce, and processed foods.</td>
<td>Plays role in acid–base balance of blood, water balance, and formation of HCl in stomach.</td>
</tr>
<tr>
<td>Magnesium</td>
<td>Important cation (Mg(^{2+})) in intracellular fluid. Excreted in urine and feces. Widespread in various foods, such as green leafy vegetables, seafood, and whole-grain cereals.</td>
<td>Required for normal functioning of muscle and nervous tissue. Participates in bone formation. Constituent of many coenzymes.</td>
</tr>

</table>

Most nutritionists recommend eating a balanced diet that includes a variety of foods rather than taking vitamin or mineral supplements, except in special circumstances. Common examples of necessary supplements include iron for women who have excessive menstrual bleeding; iron and calcium for women who are pregnant or breast-feeding; folic acid (folate) for all women who may become pregnant, to reduce the risk of fetal neural tube defects; calcium for most adults, because they do not receive the recommended amount in their diets; and vitamin B\(_{12}\) for strict vegetarians, who eat no meat. Because most North Americans...

The Principal Vitamins

<table>
<thead>
<tr>
<th>VITAMIN</th>
<th>COMMENT AND SOURCE</th>
<th>FUNCTIONS</th>
<th>DEFICIENCY SYMPTOMS AND DISORDERS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fat-soluble</td>
<td>All require bile salts and some dietary lipids for adequate absorption.</td>
<td>Maintains general health and vigor of epithelial cells. Beta-carotene acts as an antioxidant to inactivate free radicals. Essential for formation of light-sensitive pigments in photoreceptors of retina. Aids in growth of bones and teeth by helping to regulate activity of osteoblasts and osteoclasts.</td>
<td>Deficiency results in atrophy and keratinization of epithelium, leading to dry skin and hair; increased incidence of ear, sinus, respiratory, urinary, and digestive system infections; inability to gain weight; drying of cornea; and skin sores. <strong>Night blindness</strong> or decreased ability for dark adaptation. Slow and faulty development of bones and teeth. Lower incidence of ear, sinus, respiratory, urinary, and digestive system infections. Lower incidence of bone growth and repair disorders.</td>
</tr>
<tr>
<td>A</td>
<td>Formed from provitamin beta-carotene (and other provitamins) in GI tract. Stored in liver. Sources of carotene and other provitamins include orange, yellow, and green vegetables; sources of vitamin A include liver and milk.</td>
<td>Aids in growth of bones and teeth by helping to regulate activity of osteoblasts and osteoclasts.</td>
<td></td>
</tr>
<tr>
<td>D</td>
<td>Sunlight converts 7-dehydrocholesterol in the skin to cholecalciferol (vitamin D3). A liver enzyme then converts cholecalciferol to 25-hydroxycholecalciferol. A second enzyme in the kidneys converts 25-hydroxycholecalciferol to calcitriol (1,25-dihydroxycalciferol), which is the active form of vitamin D. Most is excreted in bile. Dietary sources include fish-liver oils, egg yolk, and fortified milk.</td>
<td>Essential for absorption of calcium and phosphorus from GI tract. Works with parathyroid hormone (PTH) to maintain Ca(^{2+}) homeostasis.</td>
<td>Defective utilization of calcium by bones leads to <strong>rickets</strong> in children and <strong>osteomalacia</strong> in adults. Possible loss of muscle tone.</td>
</tr>
<tr>
<td>E (tocopherols)</td>
<td>Stored in liver, adipose tissue, and muscles. Sources include fresh nuts and wheat germ, seed oils, and green leafy vegetables.</td>
<td>Inhibits catabolism of certain fatty acids that help form cell structures, especially membranes. Involved in formation of DNA, RNA, and red blood cells. May promote wound healing, contribute to the normal structure and functioning of the nervous system, and prevent scarring. May help protect liver from toxic chemicals such as carbon tetrachloride. Acts as an antioxidant to inactivate free radicals.</td>
<td>May cause oxidation of monounsaturated fats, resulting in abnormal structure and function of mitochondria, lysosomes, and plasma membranes. A possible consequence is hemolytic anemia.</td>
</tr>
<tr>
<td>K</td>
<td>Produced by intestinal bacteria. Stored in liver and spleen. Dietary sources include spinach, cauliflower, cabbage, and liver.</td>
<td>Coenzyme essential for synthesis of several clotting factors by liver, including prothrombin.</td>
<td>Delayed clotting time results in excessive bleeding.</td>
</tr>
<tr>
<td>Water-soluble</td>
<td>Dissolved in body fluids. Most are not stored in body. Excess intake is eliminated in urine.</td>
<td>Acts as coenzyme for many different enzymes that break carbon-to-carbon bonds and are involved in carbohydrate metabolism of pyruvic acid to CO(_2) and H(_2)O. Essential for synthesis of the neurotransmitter acetylcholine.</td>
<td>Improper carbohydrate metabolism leads to buildup of pyruvic and lactic acids and insufficient production of ATP for muscle and nerve cells. Deficiency leads to: (1) <strong>beriberi</strong>, partial paralysis of smooth muscle of GI tract, causing digestive disturbances; skeletal muscle paralysis; and atrophy of limbs; (2) <strong>polyneuritis</strong>, due to degeneration of myelin sheaths; impaired reflexes, impaired sense of touch, stunted growth in children, and poor appetite.</td>
</tr>
<tr>
<td>B(_1) (thiamine)</td>
<td>Rapidly destroyed by heat. Sources include whole-grain products, eggs, pork, nuts, liver, and yeast.</td>
<td></td>
<td></td>
</tr>
<tr>

<td></td>
</tr>
<tr>
<td>--------------------</td>
<td>-----------------------------------------------------------------------------------</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Water-soluble (continued)</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>B₂ (riboflavin)</strong></td>
<td>Small amounts supplied by bacteria of GI tract. Dietary sources include yeast, liver, beef, veal, lamb, eggs, whole-grain products, asparagus, peas, beets, and peanuts. Component of certain coenzymes (for example, FAD and FMN) in carbohydrate and protein metabolism, especially in cells of eye, integument, mucosa of intestine, and blood. Deficiency may lead to improper utilization of oxygen, resulting in blurred vision, cataracts, and corneal ulcerations. Also dermatitis and cracking of skin, lesions of intestinal mucosa, and one type of anemia.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Niacin</strong> (nicotinamide)</td>
<td>Derived from amino acid tryptophan. Sources include yeast, meats, liver, fish, whole-grain products, peas, beans, and nuts. Essential component of NAD and NADP, coenzymes in oxidation–reduction reactions. In lipid metabolism, inhibits production of cholesterol and assists in triglyceride breakdown. Principal deficiency is <em>pellagra</em>, characterized by dermatitis, diarrhea, and psychological disturbances.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>B₆ (pyridoxine)</strong></td>
<td>Synthesized by bacteria of GI tract. Stored in liver, muscle, and brain. Other sources include salmon, yeast, tomatoes, yellow corn, spinach, whole-grain products, liver, and yogurt. Essential coenzyme for normal amino acid metabolism. Assists production of circulating antibodies. May function as coenzyme in triglyceride metabolism. Most common deficiency symptom is dermatitis of eyes, nose, and mouth. Other symptoms are retarded growth and nausea.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>B₁₂ (cyanocobalamin)</strong></td>
<td>Only B vitamin not found in vegetables; only vitamin containing cobalt. Absorption from GI tract depends on intrinsic factor secreted by gastric mucosa. Sources include liver, kidney, milk, eggs, cheese, and meat. Coenzyme necessary for red blood cell formation, formation of the amino acid methionine, entrance of some amino acids into Krebs cycle, and manufacture of choline (used to synthesize acetylcholine). Pernicious anemia, neuropsychiatric abnormalities (ataxia, memory loss, weakness, personality and mood changes, and abnormal sensations), and impaired activity of osteoblasts.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Pantothenic acid</strong></td>
<td>Some produced by bacteria of GI tract. Stored primarily in liver and kidneys. Other sources include kidney, liver, yeast, green vegetables, and cereal. Constituent of coenzyme A, which is essential for transfer of acetyl group from pyruvic acid into the Krebs cycle, conversion of lipids and amino acids into glucose, and synthesis of cholesterol and steroid hormones. Fatigue, muscle spasms, insufficient production of adrenal steroid hormones, vomiting, and insomnia.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Folic acid</strong> (folate, folacin)</td>
<td>Synthesized by bacteria of GI tract. Dietary sources include green leafy vegetables, broccoli, asparagus, breads, dried beans, and citrus fruits. Component of enzyme systems synthesizing nitrogenous bases of DNA and RNA. Essential for normal production of red and white blood cells. Production of abnormally large red blood cells (macrocytic anemia). Higher risk of neural tube defects in babies born to folate-deficient mothers.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Biotin</strong></td>
<td>Synthesized by bacteria of GI tract. Dietary sources include yeast, liver, egg yolk, and kidneys. Essential coenzyme for conversion of pyruvic acid to oxaloacetic acid and synthesis of fatty acids and purines. Mental depression, muscular pain, dermatitis, fatigue, and nausea.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>C (ascorbic acid)</strong></td>
<td>Rapidly destroyed by heat. Some stored in glandular tissue and plasma. Sources include citrus fruits, tomatoes, and green vegetables. Promotes protein synthesis including laying down of collagen in formation of connective tissue. As coenzyme, may combine with poisons, rendering them harmless until excreted. Works with antibodies, promotes wound healing, and functions as an antioxidant. Scurvy; anemia; many symptoms related to poor collagen formation, including tender swollen gums, loosening of teeth (alveolar processes also deteriorate), poor wound healing, bleeding (vessel walls are fragile because of connective tissue degeneration), and retardation of growth.</td>
<td></td>
<td></td>

Fever

A fever is an elevation of core temperature caused by a resetting of the hypothalamic thermostat. The most common causes of fever are viral or bacterial infections and bacterial toxins; other causes are ovulation, excessive secretion of thyroid hormones, tumors, and reactions to vaccines. When phagocytes ingest certain bacteria, they are stimulated to secrete a pyrogen (PI-r6-gen; pyro- = fire; -gen = produce), a fever-producing substance. One pyrogen is interleukin-1. It circulates to the hypothalamus and induces neurons of the preoptic area to secrete prostaglandins. Some prostaglandins can reset the hypothalamic thermostat at a higher temperature, and temperature-regulating reflex mechanisms then act to bring the core body temperature up to this new setting. Antipyretics are agents that relieve or reduce fever. Examples include aspirin, acetaminophen (Tylenol), and ibuprofen (Advil), all of which reduce fever by inhibiting synthesis of certain prostaglandins.

Suppose that due to production of pyrogens the thermostat is reset at 39°C (103°F). Now the heat-promoting mechanisms (vasoconstriction, increased metabolism, shivering) are operating at full force. Thus, even though core temperature is climbing higher than normal—say, 38°C (101°F)—the skin remains cold, and shivering occurs. This condition, called a chill, is a definite sign that core temperature is rising. After several hours, core temperature reaches the setting of the thermostat, and the chills disappear. But now the body will continue to regulate temperature at 39°C (103°F). When the pyrogens disappear, the thermostat is reset at normal—37.0°C (98.6°F). Because core temperature is high in the beginning, the heat-losing mechanisms (vasodilation and sweating) go into operation to decrease core temperature. The skin becomes warm, and the person begins to sweat. This phase of the fever is called the crisis, and it indicates that core temperature is falling.

Although death results if core temperature rises above 44–46°C (112–114°F), up to a point, fever is beneficial. For example, a higher temperature intensifies the effects of interferons and the phagocytic activities of macrophages while hindering replication of some pathogens. Because fever increases heart rate, infection-fighting white blood cells are delivered to sites of infection more rapidly. In addition, antibody production and T cell proliferation increase. Moreover, heat speeds up the rate of chemical reactions, which may help body cells repair themselves more quickly.

Obesity

Obesity is body weight more than 20% above a desirable standard due to an excessive accumulation of adipose tissue. About one-third of the adult population in the United States is obese. (An athlete may be overweight due to higher-than-normal amounts of muscle tissue without being obese.) Even moderate obesity is hazardous to health; it is a risk factor in cardiovascular disease, hypertension, pulmonary disease, non-insulin-dependent diabetes mellitus, arthritis, certain cancers (breast, uterus, and colon), varicose veins, and gall-bladder disease.

In a few cases, obesity may result from trauma of or tumors in the food-regulating centers in the hypothalamus. In most cases of obesity, no specific cause can be identified. Contributing factors include genetic factors, eating habits taught early in life, overeating to relieve tension, and social customs. Studies indicate that some obese people burn fewer calories during digestion and absorption of a meal, a smaller food-induced thermogenesis effect. Additionally, obese people who lose weight require about 15% fewer calories to maintain normal body weight than do people who have never been obese. Interestingly, people who gain weight easily when deliberately fed excess calories exhibit less NEAT (nonexercise activity thermogenesis, such as occurs with fidgeting) than people who resist weight gains in the face of excess calories. Although leptin suppresses appetite and produces satiety in experimental animals, it is not deficient in most obese people.

Most surplus calories in the diet are converted to triglycerides and stored in adipose cells. Initially, the adipocytes increase in size, but at a maximal size, they divide. As a result, proliferation of adipocytes occurs in extreme obesity. The enzyme endothelial lipoprotein lipase regulates triglyceride storage. The enzyme is very active in abdominal fat but less active in hip fat. Accumulation of fat in the abdomen is associated with higher blood cholesterol level and other cardiac risk factors because adipose cells in this area appear to be more metabolically active.

Treatment of obesity is difficult because most people who are successful at losing weight gain it back within two years. Yet, even modest weight loss is associated with health benefits. Treatments for obesity include behavior modification programs, very-low-calorie diets, drugs, and surgery. Behavior modification programs, offered at many hospitals, strive to alter eating behaviors and increase exercise activity. The nutrition program includes a “heart-healthy” diet that includes abundant vegetables but is low in fats, especially saturated fats. A typical exercise program suggests walking for 30 minutes a day, five to seven times a week. Regular exercise enhances both weight loss and weight-loss maintenance. Very-low-calorie (VLC) diets include 400 to 800 kcal/day in a commercially made liquid mixture. The VLC diet is usually prescribed for 12 weeks, under close medical supervision. Two drugs are available to treat obesity. Sibutramine is an appetite suppressant that works by inhibiting reuptake of serotonin and norepinephrine in brain areas that govern eating behavior. Orlistat works by inhibiting the lipases released into the lumen of the GI tract. With less lipase activity, fewer dietary triglycerides are absorbed. For those with extreme obesity who have not responded to other treatments, a surgical procedure may be considered. The two operations most commonly performed—gastric bypass and gastroplasty—both greatly reduce the stomach size so that it can hold just a tiny quantity of food.

Medical Terminology

Heat cramps Cramps that result from profuse sweating. The salt lost in sweat causes painful contractions of muscles; such cramps tend to occur in muscles used while working but do not appear until the person relaxes once the work is done. Drinking salted liquids usually leads to rapid improvement.

Heat exhaustion (heat prostration) A condition in which the core temperature is generally normal, or a little below, and the skin is cool and moist due to profuse perspiration. Heat exhaustion is usually characterized by loss of fluid and electrolytes, especially salt (NaCl). The salt loss results in muscle cramps, dizziness, vomiting, and...
fainting; fluid loss may cause low blood pressure. Complete rest, rehydration, and electrolyte replacement are recommended.

**Heatstroke (sunstroke)** A severe and often fatal disorder caused by exposure to high temperatures, especially when the relative humidity is high, which makes it difficult for the body to lose heat. Blood flow to the skin is decreased, perspiration is greatly reduced, and body temperature rises sharply because of failure of the hypothalamic thermostat. Body temperature may reach 43°C (110°F). Treatment, which must be undertaken immediately, consists of cooling the body by immersing the victim in cool water and by administering fluids and electrolytes.

**Kwashiorkor** (kwash-ē-OR-kor) A disorder in which protein intake is deficient despite normal or nearly normal caloric intake, characterized by edema of the abdomen, enlarged liver, decreased blood pressure, low pulse rate, lower-than-normal body temperature, and sometimes mental retardation. Because the main protein in corn (zein) lacks two essential amino acids, which are needed for growth and tissue repair, many African children whose diet consists largely of cornmeal develop kwashiorkor.

**Malnutrition (mal = bad)** An imbalance of total caloric intake or intake of specific nutrients, which can be either inadequate or excessive.

**Marasmus** (mar-AZ-mus) A type of protein–calorie undernutrition that results from inadequate intake of both protein and calories. Its characteristics include retarded growth, low weight, muscle wasting, emaciation, dry skin, and thin, dry, dull hair.

---

**STUDY OUTLINE**

**Introduction (p. 977)**

1. Our only source of energy for performing biological work is the food we eat. Food also provides essential substances that we cannot synthesize.
2. Most food molecules absorbed by the gastrointestinal tract are used to supply energy for life processes, serve as building blocks during synthesis of complex molecules, or are stored for future use.

**Metabolic Reactions (p. 978)**

1. Metabolism refers to all chemical reactions of the body and is of two types: catabolism and anabolism.
2. Catabolism is the term for reactions that break down complex organic compounds into simple ones. Overall, catabolic reactions are exergonic; they produce more energy than they consume.
3. Chemical reactions that combine simple molecules into more complex ones that form the body’s structural and functional components are collectively known as anabolism. Overall, anabolic reactions are endergonic; they consume more energy than they produce.
4. The coupling of anabolism and catabolism occurs via ATP.

**Energy Transfer (p. 979)**

1. Oxidation is the removal of electrons from a substance; reduction is the addition of electrons to a substance.
2. Two coenzymes that carry hydrogen atoms during coupled oxidation-reduction reactions are nicotinamide adenine dinucleotide (NAD⁺) and flavin adenine dinucleotide (FAD).
3. ATP can be generated via substrate-level phosphorylation, oxidative phosphorylation, and photophosphorylation.

**Carbohydrate Metabolism (p. 980)**

1. During digestion, polysaccharides and disaccharides are hydrolyzed into the monosaccharides glucose (about 80%), fructose, and galactose; the latter two are then converted to glucose.
2. Some glucose is oxidized by cells to provide ATP. Glucose also can be used to synthesize amino acids, glycogen, and triglycerides.
3. Glucose moves into most body cells via facilitated diffusion through glucose transporters (GluT) and becomes phosphorylated to glucose 6-phosphate. In muscle cells, this process is stimulated by insulin. Glucose entry into neurons and hepatocytes is always "turned on."
4. Cellular respiration, the complete oxidation of glucose to CO₂ and H₂O, involves glycolysis, the Krebs cycle, and the electron transport chain.
5. Glycolysis is the breakdown of glucose into two molecules of pyruvic acid; there is a net production of two molecules of ATP.
6. When oxygen is in short supply, pyruvic acid is reduced to lactic acid; under aerobic conditions, pyruvic acid enters the Krebs cycle.
7. Pyruvic acid is prepared for entrance into the Krebs cycle by conversion to a two-carbon acetyl group followed by the addition of coenzyme A to form acetyl coenzyme A.
8. The Krebs cycle involves decarboxylations, oxidations, and reductions of various organic acids.
9. Each molecule of pyruvic acid that is converted to acetyl coenzyme A and then enters the Krebs cycle produces three molecules of CO₂, four molecules of NADH and four H⁺, one molecule of FADH₂, and one molecule of ATP.
10. The energy originally stored in glucose and then in pyruvic acid is transferred primarily to the reduced coenzymes NADH and FADH₂.
11. The electron transport chain involves a series of oxidation-reduction reactions in which the energy in NADH and FADH₂ is liberated and transferred to ATP.
12. The electron carriers include FMN, cytochromes, iron–sulfur centers, copper atoms, and coenzyme Q.
13. The electron transport chain yields a maximum of 32 or 34 molecules of ATP and six molecules of H₂O.
14. Table 25.1 on page 988 summarizes the ATP yield during cellular respiration. The complete oxidation of glucose can be represented as follows:

\[
\text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2 + 36 \text{or 38 ADPs} + 36 \text{or 38 P} \rightarrow 6\text{CO}_2 + 6\text{H}_2\text{O} + 36 \text{or 38 ATPs}
\]
15. The conversion of glucose to glycogen for storage in the liver and skeletal muscle is called glycogenesis. It is stimulated by insulin.
16. The conversion of glycogen to glucose is called glycogenolysis. It occurs between meals and is stimulated by glucagon and epinephrine.
17. Gluconeogenesis is the conversion of noncarbohydrate molecules into glucose. It is stimulated by cortisol and glucagon.

**Lipid Metabolism (p. 990)**

1. Lipoproteins transport lipids in the bloodstream. Types of lipoproteins include chylomicrons, which carry dietary lipids to adipose tissue; very-low-density lipoproteins (VLDLs), which carry triglycerides from the liver to adipose tissue; low-density lipoproteins (LDLs), which deliver cholesterol to body cells; and high-density lipoproteins (HDLs), which remove excess cholesterol from body cells and transport it to the liver for elimination.
2. Cholesterol in the blood comes from two sources: from food and from synthesis by the liver.
3. Lipids may be oxidized to produce ATP or stored as triglycerides in adipose tissue, mostly in the subcutaneous layer.
4. A few lipids are used as structural molecules or to synthesize essential molecules.
5. Adipose tissue contains lipases that catalyze the deposition of triglycerides from chylomicrons and hydrolyze triglycerides into fatty acids and glycerol.
6. In lipolysis, triglycerides are split into fatty acids and glycerol and released from adipose tissue under the influence of epinephrine, norepinephrine, cortisol, thyroid hormones, and insulin-like growth factors.
7. Glycerol can be converted into glucose by conversion into glycerol-aldehyde 3-phosphate.
8. In beta-oxidation of fatty acids, carbon atoms are removed in pairs from fatty acid chains; the resulting molecules of acetyl coenzyme A enter the Krebs cycle.
9. The conversion of glucose or amino acids into lipids is called lipogenesis; it is stimulated by insulin.

**Protein Metabolism (p. 993)**

1. During digestion, proteins are hydrolyzed into amino acids, which enter the liver via the hepatic portal vein.
2. Amino acids, under the influence of insulin-like growth factors and insulin, enter body cells via active transport.
3. Inside cells, amino acids are synthesized into proteins that function as enzymes, hormones, structural elements, and so forth; stored as fat or glycogen; or used for energy.
4. Before amino acids can be catabolized, they must be deaminated and converted to substances that can enter the Krebs cycle.
5. Amino acids may also be converted into glucose, fatty acids, and ketone bodies.
6. Protein synthesis is stimulated by insulin-like growth factors, thyroid hormones, insulin, estrogen, and testosterone.
7. Table 25.2 on page 997 summarizes carbohydrate, lipid, and protein metabolism.

**Key Molecules at Metabolic Crossroads (p. 995)**

1. Three molecules play a key role in metabolism: glucose 6-phosphate, pyruvic acid, and acetyl coenzyme A.
2. Glucose 6-phosphate may be converted to glucose, glycogen, ribose 5-phosphate, and pyruvic acid.
3. When ATP is low and oxygen is plentiful, pyruvic acid is converted to acetyl coenzyme A; when oxygen supply is low, pyruvic acid is converted to lactic acid. Carbohydrate and protein metabolism are linked by pyruvic acid.
4. Acetyl coenzyme A is the molecule that enters the Krebs cycle; it is also used to synthesize fatty acids, ketone bodies, and cholesterol.

**Metabolic Adaptations (p. 997)**

1. During the absorptive state, ingested nutrients enter the blood and lymph from the GI tract.
2. During the absorptive state, blood glucose is oxidized to form ATP, and glucose transported to the liver is converted to glycogen or triglycerides. Most triglycerides are stored in adipose tissue. Amino acids in hepatocytes are converted to carbohydrates, fats, and proteins. Table 25.3 on page 999 summarizes the hormonal regulation of metabolism during the absorptive state.
3. During the postabsorptive state, absorption is complete and the ATP needs of the body are satisfied by nutrients already present in the body. The major task is to maintain normal blood glucose level by converting glycogen in the liver and skeletal muscle into glucose, converting glycerol into glucose, and converting amino acids into glucose. Fatty acids, ketone bodies, and amino acids are oxidized to supply ATP. Table 25.4 on page 1001 summarizes the hormonal regulation of metabolism during the postabsorptive state.
4. Fasting is going without food for a few days; starvation implies weeks or months of inadequate food intake. During fasting and starvation, fatty acids and ketone bodies are increasingly utilized for ATP production.

**Heat and Energy Balance (p. 1001)**

1. Measurement of the metabolic rate under basal conditions is called the basal metabolic rate (BMR).
2. A calorie (cal) is the amount of energy required to raise the temperature of 1 g of water 1°C.
3. Because the calorie is a relatively small unit, the kilocalorie (kcal) or Calorie (cal) is often used to measure the body’s metabolic rate and to express the energy content of foods; a kilocalorie equals 1000 calories.
4. Normal core temperature is maintained by a delicate balance between heat-producing and heat-losing mechanisms.
5. Exercise, hormones, the nervous system, body temperature, ingestion of food, age, gender, climate, sleep, and malnutrition affect metabolic rate.
6. Mechanisms of heat transfer include conduction, convection, radiation, and evaporation. Conduction is the transfer of heat between two substances or objects in contact with each other. Convection is the transfer of heat by a liquid or gas between areas of different temperatures. Radiation is the transfer of heat from a warmer object to a cooler object without physical contact. Evaporation is the conversion of a liquid to a vapor; in the process, heat is lost.
7. The hypothalamic thermostat is in the preoptic area.
8. Responses that produce, conserve, or retain heat when core temperature falls are vasoconstriction; release of epinephrine, norepinephrine, and thyroid hormones; and shivering.
9. Responses that increase heat loss when core temperature increases include vasodilation, decreased metabolic rate, and evaporation of perspiration.
10. Two nuclei in the hypothalamus that help regulate food intake are the arcuate and paraventricular nuclei. The hormone leptin, released by adipocytes, inhibits release of neuropeptide Y from the arcuate nucleus and thereby decreases food intake. Melanocortin also decreases food intake.

Nutrition (p. 1006)

1. Nutrients include water, carbohydrates, lipids, proteins, minerals, and vitamins.
2. Nutrition experts suggest dietary calories be 50–60% from carbohydrates, 30% or less from fats, and 12–15% from proteins.
3. The MyPyramid guide represents a personalized approach to making healthy food choices and maintaining regular physical activity.

SELF-QUIZ QUESTIONS
Fill in the blanks in the following statements.
1. The thermostat and food intake regulating center of the body is in the _____ of the brain.
2. The three key molecules of metabolism are ______, ______, and ______.

Indicate whether the following statements are true or false.
3. Foods that we eat are used to supply energy for life processes, serve as building blocks for synthesis reactions, or are stored for future use.
4. Vitamins A, B, D, and K are fat-soluble vitamins.

Choose the one best answer to the following questions.
5. NAD* and FAD (1) are both derivatives of B vitamins, (2) are used to carry hydrogen atoms released during oxidation reactions, (3) become NADH and FADH2 in their reduced forms, (4) act as coenzymes in the Krebs cycle, (5) are the final electron acceptors in the electron transport chain.
   (a) 1, 2, 3, 4, and 5  (b) 2, 3, and 4  (c) 2 and 4  
   (d) 1, 2, and 3  (e) 1, 2, 3, and 4

6. During glycolysis, (1) a six-carbon glucose is split into two three-carbon pyruvic acids, (2) there is a net gain of two ATP molecules, (3) two NADH molecules are oxidized, (4) moderately high levels of oxygen are needed, (5) the activity of phosphofructokinase determines the rate of the chemical reactions.
   (a) 1, 2, and 3  (b) 1 and 2  (c) 1, 2, and 5  
   (d) 2, 3, 4, and 5  (e) 1, 2, 3, and 4

7. If glucose is not needed for immediate ATP production, it can be used for (1) vitamin synthesis, (2) amino acid synthesis, (3) gluconeogenesis, (4) glycogen synthesis, (5) lipogenesis.
   (a) 1, 3, and 5  (b) 2, 4, and 5  (c) 2, 3, 4, and 5  
   (d) 1, 2, and 3  (e) 2 and 5

8. Which of the following is the correct sequence for the oxidation of glucose to produce ATP?
   (a) electron transport chain, Krebs cycle, glycolysis, formation of acetyl CoA  
   (b) Krebs cycle, formation of acetyl CoA, electron transport chain, glycolysis  
   (c) glycolysis, electron transport chain, Krebs cycle, formation of acetyl CoA

(d) glycolysis, formation of acetyl CoA, Krebs cycle, electron transport chain  
(e) formation of acetyl CoA, Krebs cycle, glycolysis, electron transport chain.

9. Which of the following would you not expect to experience during fasting or starvation?
   (a) decrease in plasma fatty acid levels  
   (b) increase in ketone body formation  
   (c) lipolysis  
   (d) increased use of ketones for ATP production in the brain  
   (e) depletion of glycogen

10. If core body temperature rises above normal, which of the following would occur to cool the body? (1) dilation of vessels in the skin, (2) increased radiation and conduction of heat to the environment, (3) increased metabolic rate, (4) evaporation of perspiration, (5) increased secretion of thyroid hormones.
    (a) 3, 4, and 5  (b) 1, 2, and 4  (c) 1, 2, and 5  
    (d) 1, 2, 3, 4 and 5  (e) 1, 2, 4, and 5

11. In which of the following situations would the metabolic rate increase? (1) sleep, (2) after ingesting food, (3) increased secretion of thyroid hormones, (4) parasympathetic nervous system stimulation, (5) fever.
    (a) 3 and 4  (b) 1, 3, and 5  (c) 2 and 3  
    (d) 2, 3, and 4  (e) 2, 3, and 5

12. Which of the following are absorptive state reactions? (1) aerobic cellular respiration, (2) glycolysis, (3) glycolysis, (4) gluconeogenesis using lactic acid, (5) lipolysis.
    (a) 1 and 2  (b) 2 and 3  (c) 3 and 4  
    (d) 4 and 5  (e) 1 and 5

13. Match the hormones with the reactions they regulate (answers may be used more than once; some reactions have more than one answer):
   (a) (g) protein catabolism  
   (b) (f) protein anabolism  
   (c) (h) growth factors

   (1) insulin  (2) cortisol  (3) glucagon  (4) thyroid hormones  
   (5) epinephrine  (6) insulinlike growth factors
14. Match the following:

- (a) deliver cholesterol to body cells for use in repair of membranes and synthesis of steroid hormones and bile salts
- (b) remove excess cholesterol from body cells and transport it to the liver for elimination
- (c) organic nutrients required in small amounts for growth and normal metabolism
- (d) the energy-transferring molecule of the body
- (e) nutrient molecules that can be oxidized to produce ATP or stored in adipose tissue
- (f) transport endogenous lipids to adipocytes for storage
- (g) the body’s preferred source for synthesizing ATP
- (h) composed of amino acids and are the primary regulatory molecules in the body
- (i) acetoacetic acid, beta-hydroxybutyric acid, and acetone
- (j) hormone secreted by adipocytes that acts to decrease total body-fat mass
- (k) neurotransmitter that stimulates food intake
- (l) inorganic substances that perform many vital functions in the body
- (m) carriers of electrons in the electron transport chain

- (1) leptin
- (2) minerals
- (3) glucose
- (4) lipids
- (5) proteins
- (6) neuropeptide Y
- (7) cytochromes
- (8) ketone bodies
- (9) low-density lipoproteins
- (10) ATP
- (11) vitamins
- (12) high-density lipoproteins
- (13) very low-density lipoproteins

15. Match the following:

- (a) the mechanism of ATP generation that links chemical reactions with pumping of hydrogen ions
- (b) the removal of electrons from an atom or molecule resulting in a decrease in potential energy
- (c) the transfer of an amino group from an amino acid to a substance such as pyruvic acid
- (d) the formation of glucose from noncarbohydrate sources
- (e) refers to all the chemical reactions in the body
- (f) the oxidation of glucose to produce ATP
- (g) the splitting of a triglyceride into glycerol and fatty acids
- (h) the synthesis of lipids
- (i) the addition of electrons to a molecule resulting in an increase in potential energy content of the molecule
- (j) the formation of ketone bodies
- (k) the breakdown of glycogen back to glucose
- (l) exergonic chemical reactions that break down complex organic molecules into simpler ones
- (m) overall rate at which metabolic reactions use energy
- (n) the breakdown of glucose into two molecules of pyruvic acid
- (o) removal of CO₂ from a molecule
- (p) endergonic chemical reactions that combine simple molecules and monomers to make more complex ones
- (q) the addition of a phosphate group to a molecule
- (r) the removal of the amino group from an amino acid
- (s) the cleavage of one pair of carbon atoms at a time from a fatty acid
- (t) the conversion of glucose into glycogen
ANSWERS TO FIGURE QUESTIONS

25.1 In pancreatic acinar cells, anabolism predominates because the primary activity is synthesis of complex molecules (digestive enzymes).

25.2 Glycolysis is also called anaerobic cellular respiration.

25.3 The reactions of glycolysis consume two molecules of ATP but generate four molecules of ATP, for a net gain of two.

25.4 Kinases are enzymes that phosphorylate (add phosphate to) their substrate.

25.5 Glycolysis occurs in the cytosol.

25.6 CO₂ is given off during the production of acetyl coenzyme A and during the Krebs cycle. It diffuses into the blood, is transported by the blood to the lungs, and is exhaled.

25.7 The production of reduced coenzymes is important in the Krebs cycle because they will subsequently yield ATP in the electron transport chain.

25.8 The energy source that powers the proton pumps is electrons provided by NADH + H⁺.

25.9 The concentration of H⁺ is highest in the space between the inner and outer mitochondrial membranes.

25.10 During the complete oxidation of one glucose molecule, six molecules of O₂ are used and six molecules of CO₂ are produced.

25.11 Skeletal muscle fibers can synthesize glycogen, but they cannot release glucose into the blood because they lack the enzyme phosphatase required to remove the phosphate group from glucose.

25.12 Hepatocytes can carry out gluconeogenesis and glycogenesis.

25.13 LDLs deliver cholesterol to body cells.

25.14 Hepatocytes and adipose cells carry out lipogenesis, beta oxidation, and lipolysis; hepatocytes carry out ketogenesis.

25.15 Before an amino acid can enter the Krebs cycle, an amino group must be removed via deamination.

25.16 Acetyl coenzyme A is the gateway into the Krebs cycle for molecules being oxidized to generate ATP.

25.17 Reactions of the absorptive state are mainly anabolic.

25.18 Processes that directly elevate blood glucose during the postabsorptive state include lipolysis (in adipocytes and hepatocytes), gluconeogenesis (in hepatocytes), and glycogenolysis (in hepatocytes).

25.19 Exercise, the sympathetic nervous system, hormones (epinephrine, norepinephrine, thyroxine, testosterone, human growth hormone), elevated body temperature, and ingestion of food increase metabolic rate, which results in an increase in body temperature.

25.20 The wider base of each band represents foods with little or no solid fats or added sugars.
The urinary system contributes to homeostasis by altering blood composition, pH, volume, and pressure; maintaining blood osmolarity; excreting wastes and foreign substances; and producing hormones.

The urinary system consists of two kidneys, two ureters, one urinary bladder, and one urethra (Figure 26.1). After the kidneys filter blood plasma, they return most of the water and solutes to the bloodstream. The remaining water and solutes constitute urine, which passes through the ureters and is stored in the urinary bladder until it is excreted from the body through the urethra.

Nephrology (nep-ROL-ē-jē; nephr- = kidney; -ology = study of) is the scientific study of the anatomy, physiology, and pathology of the kidneys. The branch of medicine that deals with the male and female urinary systems and the male reproductive system is called urology (ū-ROL-ē-jē; uro- = urine). A physician who specializes in this branch of medicine is called a urologist (ū-ROL-ē-jist).
**Figure 26.1 Organs of the urinary system in a female.** (See Tortora, *A Photographic Atlas of the Human Body, Second Edition*, Figure 13.2.)

Urine formed by the kidneys passes first into the ureters, then to the urinary bladder for storage, and finally through the urethra for elimination from the body.

**Functions of the Urinary System**

1. The kidneys regulate blood volume and composition, help regulate blood pressure, synthesize glucose, release erythropoietin, participate in vitamin D synthesis, and excrete wastes by forming urine.
2. The ureters transport urine from the kidneys to the urinary bladder.
3. The urinary bladder stores urine.
4. The urethra discharges urine from the body.

Which organs constitute the urinary system?
OVERVIEW OF KIDNEY FUNCTIONS

OBJECTIVE

• List the functions of the kidneys.

The kidneys do the major work of the urinary system. The other parts of the system are mainly passageways and storage areas. Functions of the kidneys include the following:

• Regulation of blood ionic composition. The kidneys help regulate the blood levels of several ions, most importantly sodium ions (Na⁺), potassium ions (K⁺), calcium ions (Ca²⁺), chloride ions (Cl⁻), and phosphate ions (HPO₄²⁻).

• Regulation of blood pH. The kidneys excrete a variable amount of hydrogen ions (H⁺) into the urine and conserve bicarbonate ions (HCO₃⁻), which are an important buffer of H⁺ in the blood. Both of these activities help regulate blood pH.

• Regulation of blood volume. The kidneys adjust blood volume by conserving or eliminating water in the urine. An increase in blood volume increases blood pressure; a decrease in blood volume decreases blood pressure.

• Regulation of blood pressure. The kidneys also help regulate blood pressure by secreting the enzyme renin, which activates the renin–angiotensin–aldosterone pathway (see Figure 18.16 on page 667). Increased renin causes an increase in blood pressure.

• Maintenance of blood osmolarity. By separately regulating loss of water and loss of solutes in the urine, the kidneys maintain a relatively constant blood osmolarity close to 300 milliosmoles per liter (mOsm/Liter).*

• Production of hormones. The kidneys produce two hormones. Calcitriol, the active form of vitamin D, helps regulate calcium homeostasis (see Figure 18.14 on page 664), and erythropoietin stimulates the production of red blood cells (see Figure 19.5 on page 697).

• Regulation of blood glucose level. Like the liver, the kidneys can use the amino acid glutamine in gluconeogenesis, the synthesis of new glucose molecules. They can then release glucose into the blood to help maintain a normal blood glucose level.

• Excretion of wastes and foreign substances. By forming urine, the kidneys help excrete wastes—substances that have no useful function in the body. Some wastes excreted in urine result from metabolic reactions in the body. These include ammonia and urea from the deamination of amino acids; bilirubin from the catabolism of hemoglobin; creatinine from the breakdown of creatine phosphate in muscle fibers; and uric acid from the catabolism of nucleic acids. Other wastes excreted in urine are foreign substances from the diet, such as drugs and environmental toxins.

CHECKPOINT

1. What are wastes, and how do the kidneys participate in their removal from the body?

ANATOMY AND HISTOLOGY OF THE KIDNEYS

OBJECTIVES

• Describe the external and internal gross anatomical features of the kidneys.

• Trace the path of blood flow through the kidneys.

• Describe the structure of renal corpuscles and renal tubules.

The paired kidneys are reddish, kidney-bean-shaped organs located just above the waist between the peritoneum and the posterior wall of the abdomen. Because their position is posterior to the peritoneum of the abdominal cavity, they are said to be retroperitoneal (re'trō-per-i-tō-NÉ-al; retro- = behind) organs (Figure 26.2). The kidneys are located between the levels of the last thoracic and third lumbar vertebrae, a position where they are partially protected by the eleventh and twelfth pairs of ribs. The right kidney is slightly lower than the left (see Figure 26.1) because the liver occupies considerable space on the right side superior to the kidney.

External Anatomy of the Kidneys

A typical adult kidney is 10–12 cm (4–5 in.) long, 5–7 cm (2–3 in.) wide, and 3 cm (1 in.) thick—about the size of a bar of bath soap—and has a mass of 135–150 g (4.5–5 oz). The concave medial border of each kidney faces the vertebral column (see Figure 26.1). Near the center of the concave border is an indentation called the renal hilum (see Figure 26.3), through which the ureter emerges from the kidney along with blood vessels, lymphatic vessels, and nerves.

Three layers of tissue surround each kidney (Figure 26.2). The deep layer, the renal capsule (ren- = kidney), is a smooth, transparent sheet of dense irregular connective tissue that is continuous with the outer coat of the ureter. It serves as a barrier against trauma and helps maintain the shape of the kidney. The middle layer, the adipose capsule, is a mass of fatty tissue surrounding the renal capsule. It also protects the kidney from trauma and holds it firmly in place within the abdominal cavity. The superficial layer, the renal fascia, is another thin layer of dense irregular connective tissue that anchors the kidney to the surrounding organs.

*The osmolarity of a solution is a measure of the total number of dissolved particles per liter of solution. The particles may be molecules, ions, or a mixture of both. To calculate osmolarity, multiply molarity (see page 40) by the number of particles per molecule, once the molecule dissolves. A similar term, osmolality, is the number of particles of solute per kilogram of water. Because it is easier to measure volumes of solutions than to determine the mass of water they contain, osmolality is used more commonly than osmolarity. Most body fluids and solutions used clinically are dilute, in which case there is less than a 1% difference between the two measures.
Figure 26.2 Position and coverings of the kidneys. (See Tortora, A Photographic Atlas of the Human Body, Second Edition, Figure 13.3.) The kidneys are surrounded by a renal capsule, adipose capsule, and renal fascia.

Why are the kidneys said to be retroperitoneal?
the surrounding structures and to the abdominal wall. On the anterior surface of the kidneys, the renal fascia is deep to the peritoneum.

**Clinical Connection**

Nephroptosis (Floating Kidney)

Nephroptosis (néf-rōp-Tō-sis; ptosis = falling), or floating kidney, is an inferior displacement or dropping of the kidney. It occurs when the kidney slips from its normal position because it is not securely held in place by adjacent organs or its covering of fat. Nephroptosis develops most often in very thin people whose adipose capsule or renal fascia is deficient. It is dangerous because the ureret may kink and block urine flow. The resulting backup of urine puts pressure on the kidney, which damages the tissue. Twisting of the ureter also causes pain. Nephroptosis is very common; about one in four people has some degree of weakening of the fibrous bands that hold the kidney in place. It is 10 times more common in females than males. Because it happens during life it is very easy to distinguish from congenital anomalies.

Internal Anatomy of the Kidneys

A frontal section through the kidney reveals two distinct regions: a superficial, light red area called the renal cortex (cortex = rind or bark) and a deep, darker reddish-brown inner region called the renal medulla (medulla = inner portion) (Figure 26.3). The renal medulla consists of several cone-shaped renal pyramids. The base (wider end) of each pyramid faces the renal cortex, and its apex (narrower end), called a [renal papilla](#), points toward the renal hilum. The renal cortex is the smooth-textured area extending from the renal capsule to the bases of the renal pyramids and into the spaces between them. It is divided into an outer [cortical zone](#) and an inner [juxtamedullary zone](#). Those portions of the renal cortex that extend between renal pyramids are called renal columns. A renal lobe consists of a renal pyramid, its overlying area of renal cortex, and one-half of each adjacent renal column.

Together, the renal cortex and renal pyramids of the renal medulla constitute the parenchyma (functional portion) of the kidney. Within the parenchyma are the functional units of the kidney—about 1 million microscopic structures called nephrons (néf-rōn’s). Urine formed by the nephrons drains into large [papillary ducts](#), which extend through the renal papillae of the pyramids. The papillary ducts drain into cuplike structures called minor and major calyces (kā-li-sēz = cups; singular is calyx). Each kidney has 8 to 18 minor calyces and 2 or 3 major calyces. A minor calyx receives urine from the papillary ducts of one renal papilla and delivers it to a major calyx. From the major calyces, urine drains into a single large cavity called the renal pelvis (pelv- = basin) and then out through the ureter to the urinary bladder.

The hilum expands into a cavity within the kidney called the renal sinus, which contains part of the renal pelvis, the calyces, and branches of the renal blood vessels and nerves. Adipose tissue helps stabilize the position of these structures in the renal sinus.

**Blood and Nerve Supply of the Kidneys**

Because the kidneys remove wastes from the blood and regulate its volume and ionic composition, it is not surprising that they are abundantly supplied with blood vessels. Although the kidneys constitute less than 0.5% of total body mass, they receive 20–25% of the resting cardiac output via the right and left [renal arteries](#). In adults, renal blood flow, the blood flow through both kidneys, is about 1200 mL per minute.

Within the kidney, the renal artery divides into several [segmental arteries](#), which supply different segments (areas) of the kidney. Each segmental artery gives off several branches that enter the parenchyma and pass through the renal columns between the renal pyramids as the [interlobar arteries](#). At the bases of the renal pyramids, the interlobar arteries arch between the renal medulla and cortex; here they are known as the [arcuate arteries](#) (AR-kū-āt = shaped like a bow). Divisions of the arcuate arteries produce a series of [interlobular arteries](#). These arteries are so named because they pass between renal lobules. Interlobular arteries enter the renal cortex and give off branches called [afferent arterioles](#) (af- = toward; -ferrent = to carry).

Each nephron receives one afferent arteriole, which divides into a tangled, ball-shaped capillary network called the glomerulus (glō-MER-u-lus = little ball; plural is glomeruli). The glomerular capillaries then reunite to form an [efferent arteriole](#) (ef- = out) that carries blood out of the glomerulus. Glomerular capillaries are unique among capillaries in the body because they are positioned between two arterioles, rather than between an arteriole and a venule. Because they are capillary networks and they also play an important role in urine formation, the glomeruli are considered part of both the cardiovascular and the urinary systems.

The efferent arterioles divide to form the [peritubular capillaries](#) (peri- = around), which surround tubular parts of the nephron in the renal cortex. Extending from some efferent arterioles are long loop-shaped capillaries called vasa recta (VA-sa REK-ta; vasa = vessels; recta = straight) that supply tubular portions of the nephron in the renal medulla (see Figure 26.5b).

The peritubular capillaries eventually reunite to form [peritubular venules](#) and then [interlobular veins](#), which also receive blood from the vasa recta. Then the blood drains through the arcuate veins to the interlobar veins running between the renal pyramids. Blood leaves the kidney through a single [renal vein](#) that exits at the renal hilum and carries venous blood to the inferior vena cava.

Many renal nerves originate in the renal ganglion and pass through the renal plexus into the kidneys along with the renal arteries. Renal nerves are part of the sympathetic division of the autonomic nervous system. Most are vasomotor nerves that...
What structures pass through the renal hilum?
The renal arteries deliver 20–25% of the resting cardiac output to the kidneys.

The nephron

Parts of a Nephron

Nephrons are the functional units of the kidneys. Each nephron (Figure 26.5) consists of two parts: a renal corpuscle (KOR-pus-sul = tiny body), where blood plasma is filtered, and a renal tubule into which the filtered fluid passes. The two components of a renal corpuscle are the glomerulus (capillary network) and the glomerular (Bowman’s) capsule, a double-walled epithelial cup that surrounds the glomerular capillaries. Blood plasma is filtered in the glomerular capsule, and then the filtered fluid passes into the renal tubule, which has three main sections. In the order that fluid passes through them, the renal tubule consists of a (1) proximal convoluted tubule, (2) loop of Henle (nephron loop), and (3) distal convoluted tubule. Proximal denotes the part of the tubule attached to the glomerular capsule, and distal denotes the part that is further away. Convoluted means the tubule is tightly coiled rather than straight. The renal corpuscle and both convoluted tubules lie within the renal medulla.
**Figure 26.5** The structure of nephrons and associated blood vessels. Note that the collecting duct and papillary duct are not part of a nephron. (a) A cortical nephron. (b) A juxtamedullary nephron.

Nephrons are the functional units of the kidneys.
nephrons. Their renal corpuscles lie in the outer portion of the renal cortex, and they have short loops of Henle that lie mainly in the cortex and penetrate only into the outer region of the renal medulla (Figure 26.5a). The short loops of Henle receive their blood supply from peritubular capillaries that arise from efferent arterioles. The other 15–20% of the nephrons are juxtamedullary nephrons (juxta- = near to). Their renal corpuscles lie deep in the cortex, close to the medulla, and they have a long loop of Henle that extends into the deepest region of the medulla (Figure 26.5b). Long loops of Henle receive their blood supply from peritubular capillaries and from the vasa recta that arise from efferent arterioles. In addition, the ascending limb of the loop of Henle of juxtamedullary nephrons consists of two portions: a thin ascending limb followed by a thick ascending
limb (Figure 26.5b). The lumen of the thin ascending limb is the same as in other areas of the renal tubule; it is only the epithelium that is thinner. Nephrons with long loops of Henle enable the kidneys to excrete very dilute or very concentrated urine (described on pages 1042–1046).

**Histology of the Nephron and Collecting Duct**

A single layer of epithelial cells forms the entire wall of the glomerular capsule, renal tubule, and ducts. However, each part has distinctive histological features that reflect its particular functions. We will discuss them in the order that fluid flows through them: glomerular capsule, renal tubule, and collecting duct.

**Glomerular Capsule**

The glomerular (Bowman’s) capsule consists of visceral and parietal layers (Figure 26.6a). The visceral layer consists of modified simple squamous epithelial cells called podocytes (PO-dō-sīts; podo- = foot; -cytes = cells).

**Figure 26.6** Histology of a renal corpuscle.

A renal corpuscle consists of a glomerular (Bowman’s) capsule and a glomerulus.

Is the photomicrograph in (b) from a section through the renal cortex or renal medulla? How can you tell?
The many footlike projections of these cells (pedicels) wrap around the single layer of endothelial cells of the glomerular capillaries and form the inner wall of the capsule. The parietal layer of the glomerular capsule consists of simple squamous epithelium and forms the outer wall of the capsule. Fluid filtered from the glomerular capillaries enters the **capsular (Bowman’s) space**, the space between the two layers of the glomerular capsule. Think of the glomerulus as a fist punched into a limp balloon (the glomerular capsule) until the fist is covered by two layers of balloon (visceral and parietal layers) with a space in between (the capsular space).

**Renal Tubule and Collecting Duct**

Table 26.1 illustrates the histology of the cells that form the renal tubule and collecting duct. In the proximal convoluted tubule, the cells are simple cuboidal epithelial cells with a prominent brush border of microvilli on their apical surface (surface facing the lumen). These microvilli, like those of the small intestine, increase the surface area for reabsorption and secretion. The descending limb of the loop of Henle and the first part of the ascending limb of the loop of Henle (the thin ascending limb) are composed of simple squamous epithelium. (Recall that cortical or short-loop nephrons lack the thin ascending limb.) The thick ascending limb of the loop of Henle is composed of simple cuboidal to low columnar epithelium.

In each nephron, the final part of the ascending limb of the loop of Henle makes contact with the afferent arteriole serving that renal corpuscle (Figure 26.6a). Because the columnar tubule cells in this region are crowded together, they are known as the **macula densa** (*macula* = spot; *densa* = dense). Alongside the macula densa, the wall of the afferent arteriole (and sometimes the efferent arteriole) contains modified smooth muscle fibers.

called juxtaglomerular (JG) cells. Together with the macula densa, they constitute the juxtaglomerular apparatus (JGA). As you will see later, the JGA helps regulate blood pressure within the kidneys. The distal convoluted tubule (DCT) begins a short distance past the macula densa. In the last part of the DCT and continuing into the collecting ducts, two different types of cells are present. Most are principal cells, which have receptors for both antidiuretic hormone (ADH) and aldosterone, two hormones that regulate their functions. A smaller number are intercalated cells, which play a role in the homeostasis of blood pH. The collecting ducts drain into large papillary ducts, which are lined by simple columnar epithelium.

The number of nephrons is constant from birth. Any increase in kidney size is due solely to the growth of individual nephrons. If nephrons are injured or become diseased, new ones do not form. Signs of kidney dysfunction usually do not become apparent until function declines to less than 25% of normal because the remaining functional nephrons adapt to handle a larger-than-normal load. Surgical removal of one kidney, for example, stimulates hypertrophy (enlargement) of the remaining kidney, which eventually is able to filter blood at 80% of the rate of two normal kidneys.

CHECKPOINT

2. Why are the kidneys said to be retroperitoneal?
3. What are the major parts of a nephron?
4. How do cortical nephrons and juxtamedullary nephrons differ structurally?
5. Where is the juxtaglomerular apparatus (JGA) located, and what is its structure?

Figure 26.7 Relation of a nephron’s structure to its three basic functions: glomerular filtration, tubular reabsorption, and tubular secretion. Excreted substances remain in the urine and subsequently leave the body. For any substance S, excretion rate of S = filtration rate of S – reabsorption rate of S + secretion rate of S.

Glomerular filtration occurs in the renal corpuscle; tubular reabsorption and tubular secretion occur all along the renal tubule and collecting duct.

When cells of the renal tubules secrete the drug penicillin, is the drug being added to or removed from the bloodstream?
Solute in the fluid that drains into the renal pelvis remain in the urine and are excreted. The rate of urinary excretion of any solute is equal to its rate of glomerular filtration, plus its rate of secretion, minus its rate of reabsorption.

By filtering, reabsorbing, and secreting, nephrons help maintain homeostasis of the blood’s volume and composition. The situation is somewhat analogous to a recycling center: Garbage trucks dump refuse into an input hopper, where the smaller refuse passes onto a conveyor belt (glomerular filtration of plasma). As the conveyor belt carries the garbage along, workers remove useful items, such as aluminum cans, plastics, and glass containers (reabsorption). Other workers place additional garbage left at the center and larger items onto the conveyor belt. At the end of the belt, all remaining garbage falls into a truck for transport to the landfill (excretion of wastes in urine).

### GLOMERULAR FILTRATION

**OBJECTIVES**
- Describe the filtration membrane.
- Discuss the pressures that promote and oppose glomerular filtration.

The fluid that enters the capsular space is called the glomerular filtrate. The fraction of blood plasma in the afferent arterioles of the kidneys that becomes glomerular filtrate is the filtration fraction. Although a filtration fraction of 0.16–0.20 (16–20%) is typical, the value varies considerably in both health and disease. On average, the daily volume of glomerular filtrate in adults is 150 liters in females and 180 liters in males. More than 99% of the glomerular filtrate returns to the bloodstream via tubular reabsorption, so only 1–2 liters (about 1–2 qt) are excreted as urine.

**The Filtration Membrane**

Together, the endothelial cells of glomerular capillaries and the podocytes, which completely encircle the capillaries, form a leaky barrier known as the filtration membrane. This sandwichlike assembly permits filtration of water and small solutes but prevents filtration of most plasma proteins, blood cells, and platelets. Substances filtered from the blood cross three barriers—a glomerular endothelial cell, the basal lamina, and a filtration slit formed by a podocyte (Figure 26.8):

1. Glomerular endothelial cells are quite leaky because they have large fenestrations (pores) that measure 0.07–0.1 μm in diameter. This size permits all solutes in blood plasma to exit glomerular capillaries but prevents filtration of blood cells and platelets. Located among the glomerular capillaries and in the cleft between afferent and efferent arterioles are mesangial cells (mes- = in the middle; angi = blood vessel) (see Figure 26.6a). These contractile cells help regulate glomerular filtration.
2. The basal lamina, a layer of acellular material between the endothelium and the podocytes, consists of minute collagen fibers and proteoglycans in a glycoprotein matrix; it prevents filtration of larger plasma proteins.
3. Extending from each podocyte are thousands of footlike processes termed pedicels (PED-i-sels = little feet) that wrap around glomerular capillaries. The spaces between pedicels are the filtration slits. A thin membrane, the slit membrane, extends across each filtration slit; it permits the passage of molecules having a diameter smaller than 0.006–0.007 μm, including water, glucose, vitamins, amino acids, very small plasma proteins, ammonia, urea, and ions. Less than 1% of albumin, the most plentiful plasma protein, passes the slit membrane because, with a diameter of 0.007μm, it is slightly too big to get through.

The principle of filtration—the use of pressure to force fluids and solutes through a membrane—is the same in glomerular capillaries as in capillaries elsewhere in the body (see Starling’s law of the capillaries, page 770). However, the volume of fluid filtered by the renal corpuscle is much larger than in other capillaries of the body for three reasons:

1. Glomerular capillaries present a large surface area for filtration because they are long and extensive. The mesangial cells regulate how much of this surface area is available for filtration. When mesangial cells are relaxed, surface area is maximal, and glomerular filtration is very high. Contraction of mesangial cells reduces the available surface area, and glomerular filtration decreases.
2. The filtration membrane is thin and porous. Despite having several layers, the thickness of the filtration membrane is only 0.1 μm. Glomerular capillaries also are about 50 times leakier than capillaries in most other tissues, mainly because of their large fenestrations.
3. Glomerular capillary blood pressure is high. Because the efferent arteriole is smaller in diameter than the afferent arteriole, resistance to the outflow of blood from the glomerulus is high. As a result, blood pressure in glomerular capillaries is considerably higher than in capillaries elsewhere in the body.

### Net Filtration Pressure

Glomerular filtration depends on three main pressures. One pressure promotes filtration and two pressures oppose filtration (Figure 26.9 on page 1032).

1. Glomerular blood hydrostatic pressure (GBHP) is the blood pressure in glomerular capillaries. Generally, GBHP is about 55 mmHg. It promotes filtration by forcing water and solutes in blood plasma through the filtration membrane.
2. Capsular hydrostatic pressure (CHP) is the hydrostatic pressure exerted against the filtration membrane by fluid already in the capsular space and renal tubule. CHP opposes filtration and represents a “back pressure” of about 15 mmHg.
Figure 26.8 The filtration membrane. The size of the endothelial fenestrations and filtration slits in (a) have been exaggerated for emphasis.

During glomerular filtration, water and solutes pass from blood plasma into the capsular space.

1. Fenestration (pore) of glomerular endothelial cell: prevents filtration of blood cells but allows all components of blood plasma to pass through.
2. Basal lamina of glomerulus: prevents filtration of larger proteins.

Which part of the filtration membrane prevents red blood cells from entering the capsular space?
Blood colloid osmotic pressure (BCOP), which is due to the presence of proteins such as albumin, globulins, and fibrinogen in blood plasma, also opposes filtration. The average BCOP in glomerular capillaries is 30 mmHg.

Net filtration pressure (NFP), the total pressure that promotes filtration, is determined as follows:

Net Filtration Pressure (NFP) = GBHP – CHP – BCOP

By substituting the values just given, normal NFP may be calculated:

NFP = 55 mmHg – 15 mmHg – 30 mmHg
 = 10 mmHg

Thus, a pressure of only 10 mmHg causes a normal amount of blood plasma (minus plasma proteins) to filter from the glomerulus into the capsular space.

**Clinical Connection** Loss of Plasma Proteins in Urine Causes Edema

In some kidney diseases, glomerular capillaries are damaged and become so permeable that plasma proteins enter glomerular filtrate. As a result, the filtrate exerts a colloid osmotic pressure that draws water out of the blood. In this situation, the NFP increases, which means more fluid is filtered. At the same time, blood colloid osmotic pressure decreases because plasma proteins are being lost in the urine. Because more fluid filters out of blood capillaries into tissues throughout the body than returns via reabsorption, blood volume decreases and interstitial fluid volume increases. Thus, loss of plasma proteins in urine causes edema, an abnormally high volume of interstitial fluid.

**Glomerular Filtration Rate**

The amount of filtrate formed in all the renal corpuscles of both kidneys each minute is the glomerular filtration rate (GFR). In adults, the GFR averages 125 mL/min in males and 105 mL/min in females. Homeostasis of body fluids requires that the kidneys maintain a relatively constant GFR. If the GFR is too high, needed substances may pass so quickly through the renal tubules that some are not reabsorbed and are lost in the urine. If the GFR is too low, nearly all the filtrate may be reabsorbed and certain waste products may not be adequately excreted.

GFR is directly related to the pressures that determine net filtration pressure; any change in net filtration pressure will affect GFR. Severe blood loss, for example, reduces mean arterial blood pressure and decreases the glomerular blood hydrostatic pressure. Filtration ceases if glomerular blood hydrostatic pressure falls below 50 mmHg.

Suppose a tumor is pressing on and obstructing the right ureter. What effect might this have on CHP and thus on NFP in the right kidney? Would the left kidney also be affected?
pressure drops to 45 mmHg because the opposing pressures add up to 45 mmHg. Amazingly, when systemic blood pressure rises above normal, net filtration pressure and GFR increase very little. GFR is nearly constant when the mean arterial blood pressure is anywhere between 80 and 180 mmHg.

The mechanisms that regulate glomerular filtration rate operate in two main ways: (1) by adjusting blood flow into and out of the glomerulus and (2) by altering the glomerular capillary surface area available for filtration. GFR increases when blood flow into the glomerular capillaries increases. Coordinated control of the diameter of both afferent and efferent arterioles regulates glomerular blood flow. Constriction of the afferent arteriole decreases blood flow into the glomerulus; dilation of the afferent arteriole increases it. Three mechanisms control GFR: renal autoregulation, neural regulation, and hormonal regulation.

Renal Autoregulation of GFR
The kidneys themselves help maintain a constant renal blood flow and GFR despite normal, everyday changes in blood pressure, like those that occur during exercise. This capability is called renal autoregulation and consists of two mechanisms—the myogenic mechanism and tubuloglomerular feedback. Working together, they can maintain nearly constant GFR over a wide range of systemic blood pressures.

The myogenic mechanism (myo- = muscle; -genic = producing) occurs when stretching triggers contraction of smooth muscle cells in the walls of afferent arterioles. As blood pressure rises, GFR also rises because renal blood flow increases. However, the elevated blood pressure stretches the walls of the afferent arterioles. In response, smooth muscle fibers in the wall of the afferent arteriole contract, which narrows the arteriole’s lumen. As a result, renal blood flow decreases, thus reducing GFR to its previous level. Conversely, when arterial blood pressure drops, the smooth muscle cells are stretched less and thus relax. The afferent arterioles dilate, renal blood flow increases, and GFR increases. The myogenic mechanism normalizes renal blood flow and GFR within seconds after a change in blood pressure.

The second contributor to renal autoregulation, tubuloglomerular feedback, is so named because part of the renal tubules—the macula densa—provides feedback to the glomerulus (Figure 26.10). When GFR is above normal due to elevated systemic blood pressure, filtered fluid flows more rapidly along the renal tubules. As a result, the proximal convoluted tube and loop of Henle have less time to reabsorb Na⁺, Cl⁻, and water. Macula densa cells are thought to detect the increased delivery of Na⁺, Cl⁻, and water and to inhibit release of nitric oxide (NO) from cells in the juxtaglomerular apparatus (JGA). Because NO causes vasodilation, afferent arterioles constrict when the level of NO declines. As a result, less blood flows into the glomerular capillaries, and GFR decreases. When blood pressure falls, causing GFR to be lower than normal, the opposite sequence of events occurs, although to a lesser degree. Tubuloglomerular feedback operates more slowly than the myogenic mechanism.

Neural Regulation of GFR
Like most blood vessels of the body, those of the kidneys are supplied by sympathetic ANS fibers that release norepinephrine. Norepinephrine causes vasoconstriction through the activation of α₁ receptors, which are particularly plentiful in the smooth muscle fibers of afferent arterioles. At rest, sympathetic stimulation is moderately low, the afferent and efferent arterioles are dilated, and renal autoregulation of GFR prevails. With moderate sympathetic
stimulation, both afferent and efferent arterioles constrict to the same degree. Blood flow into and out of the glomerulus is restricted to the same extent, which decreases GFR only slightly. With greater sympathetic stimulation, however, as occurs during exercise or hemorrhage, vasoconstriction of the afferent arterioles predominates. As a result, blood flow into glomerular capillaries is greatly decreased, and GFR drops. This lowering of renal blood flow has two consequences: (1) It reduces urine output, which helps conserve blood volume. (2) It permits greater blood flow to other body tissues.

**Hormonal Regulation of GFR**

Two hormones contribute to regulation of GFR. Angiotensin II reduces GFR; atrial natriuretic peptide (ANP) increases GFR. Angiotensin II is a very potent vasoconstrictor that narrows both afferent and efferent arterioles and reduces renal blood flow, thereby decreasing GFR. Cells in the atria of the heart secrete atrial natriuretic peptide (ANP). Stretching of the atria, as occurs when blood volume increases, stimulates secretion of ANP. By causing relaxation of the glomerular mesangial cells, ANP increases the capillary surface area available for filtration. Glomerular filtration rate rises as the surface area increases.

Table 26.2 summarizes the regulation of glomerular filtration rate.

**CHECKPOINT**

6. If the urinary excretion rate of a drug such as penicillin is greater than the rate at which it is filtered at the glomerulus, how else is it getting into the urine?

7. What is the major chemical difference between blood plasma and glomerular filtrate?

8. Why is there much greater filtration through glomerular capillaries than through capillaries elsewhere in the body?

9. Write the equation for the calculation of net filtration pressure (NFP) and explain the meaning of each term.

10. How is glomerular filtration rate regulated?

**TUBULAR REABSORPTION AND TUBULAR SECRETION**

**OBJECTIVES**

- Describe the routes and mechanisms of tubular reabsorption and secretion.
- Describe how specific segments of the renal tubule and collecting duct reabsorb water and solutes.
- Describe how specific segments of the renal tubule and collecting duct secrete solutes into the urine.

**Principles of Tubular Reabsorption and Secretion**

The volume of fluid entering the proximal convoluted tubules in just half an hour is greater than the total blood plasma volume because the normal rate of glomerular filtration is so high. Obviously some of this fluid must be returned somehow to the bloodstream. Reabsorption—the return of most of the filtered water and many of the filtered solutes to the bloodstream—is the second basic function of the nephron and collecting duct. Normally, about 99% of the filtered water is reabsorbed. Epithelial cells all along the renal tubule and duct carry out reabsorption, but proximal convoluted tubule cells make the largest contribution. Solutes that are reabsorbed by both active and passive processes include glucose, amino acids, urea, and ions such as Na⁺ (sodium), K⁺ (potassium), Ca²⁺ (calcium), Cl⁻ (chloride), HCO₃⁻ (bicarbonate), and HPO₄²⁻ (phosphate). Once fluid passes through the proximal convoluted tubule, cells located more distally fine-tune the reabsorption processes to
maintain homeostatic balances of water and selected ions. Most small proteins and peptides that pass through the filter also are reabsorbed, usually via pinocytosis. To appreciate the magnitude of tubular reabsorption, look at Table 26.3 and compare the amounts of substances that are filtered, reabsorbed, and excreted in urine.

The third function of nephrons and collecting ducts is tubular secretion, the transfer of materials from the blood and tubule cells into tubular fluid. Secreted substances include hydrogen ions (H+)
, K+, ammonium ions (NH₄+), creatinine, and certain drugs such as penicillin. Tubular secretion has two important outcomes: (1) The secretion of H+ helps control blood pH. (2) The secretion of other substances helps eliminate them from the body.

As a result of tubular secretion, certain substances pass from blood into urine and may be detected by a urinalysis (see page 1047). It is especially important to test athletes for the presence of performance-enhancing drugs such as anabolic steroids, plasma expanders, erythropoietin, hCG, hGH, and amphetamines. Urine tests can also be used to detect the presence of alcohol or illegal drugs such as marijuana, cocaine, and heroin.

**Reabsorption Routes**

A substance being reabsorbed from the fluid in the tubule lumen can take one of two routes before entering a peritubular capillary: It can move between adjacent tubule cells or through an individual tubule cell (Figure 26.11). Along the renal tubule, tight junctions surround and join neighboring cells to one another, much like the plastic rings that hold a six-pack of soda cans together. The apical membrane (the tops of the soda cans) contacts the tubular fluid, and the basolateral membrane (the bottoms and sides of the soda cans) contacts interstitial fluid at the base and sides of the cell.

The tight junctions do not completely seal off the interstitial fluid from the fluid in the tubule lumen. Fluid can leak between adjacent tubule cells or through an individual tubule cell (Figure 26.11). Along the renal tubule, tight junctions surround and join neighboring cells to one another, much like the plastic rings that hold a six-pack of soda cans together. The apical membrane (the tops of the soda cans) contacts the tubular fluid, and the basolateral membrane (the bottoms and sides of the soda cans) contacts interstitial fluid at the base and sides of the cell.

the cells in a passive process known as paracellular reabsorption (para- = beside). In some parts of the renal tubule, the paracellular route is thought to account for up to 50% of the reabsorption of certain ions and the water that accompanies them via osmosis. In transcellular reabsorption (trans- = across), a substance passes from the fluid in the tubular lumen through the apical membrane of a tubule cell, across the cytosol, and out into interstitial fluid through the basolateral membrane.

Transport Mechanisms

When renal cells transport solutes out of or into tubular fluid, they move specific substances in one direction only. Not surprisingly, different types of transport proteins are present in the apical and basolateral membranes. The tight junctions form a barrier that prevents mixing of proteins in the apical and basolateral membrane compartments. Reabsorption of Na⁺ by the renal tubules is especially important because of the large number of sodium ions that pass through the glomerular filters.

Cells lining the renal tubules, like other cells throughout the body, have a low concentration of Na⁺ in their cytosol due to the activity of sodium–potassium pumps (Na⁺/K⁺ ATPases). These pumps are located in the basolateral membranes and eject Na⁺ from the renal tubule cells (Figure 26.11). The absence of sodium–potassium pumps in the apical membrane ensures that reabsorption of Na⁺ is a one-way process. Most sodium ions that cross the apical membrane will be pumped into interstitial fluid at the base and sides of the cell. The amount of ATP used by sodium–potassium pumps in the renal tubules is about 6% of the total ATP consumption of the body at rest. This may not sound like much, but it is about the same amount of energy used by the diaphragm as it contracts during quiet breathing.

As we noted in Chapter 3, transport of materials across membranes may be either active or passive. Recall that in primary active transport the energy derived from hydrolysis of ATP is used to “pump” a substance across a membrane; the sodium–potassium pump is one such pump. In secondary active transport the energy stored in an ion’s electrochemical gradient, rather than hydrolysis of ATP, drives another substance across a membrane. Secondary active transport couples the movement of an ion down its electrochemical gradient to the “uphill” movement of a second substance against its electrochemical gradient. Symporters are membrane proteins that move two or more substances in the same direction across a membrane. Antiporters move two or more substances in opposite directions across a membrane. Each type of transporter has an upper limit on how fast it can work, just as an escalator has a limit on how many people it can carry from one level to another in a given period. This limit, called the transport maximum ($T_m$), is measured in mg/min.

Solute reabsorption drives water reabsorption because all water reabsorption occurs via osmosis. About 90% of the reabsorption of water filtered by the kidneys occurs along with the reabsorption of solutes such as Na⁺, Cl⁻, and glucose. Water reabsorbed with solutes in tubular fluid is termed obligatory water reabsorption (ob-LIG-a-tor’-ë) because the water is “obliged” to follow the solutes when they are reabsorbed. This type of water reabsorption occurs in the proximal convoluted tubule and the descending limb of the loop of Henle because these segments of the nephron are always permeable to water. Reabsorption of the final 10% of the water, a total of 10–20 liters per day, is termed facultative water reabsorption (FAK-ul-tiv’-ë). The word facultative means “capable of adapting to a need.” Facultative water reabsorption is regulated by antidiuretic hormone and occurs mainly in the collecting ducts.

<tr>
<th><strong>CLINICAL CONNECTION</strong></th>
<th><strong>Glucosuria</strong></th>
</tr>
</thead>
</table>
| When the blood concentration of glucose is above 200 mg/mL, the renal sympotmers cannot work fast enough to reabsorb all the glucose that enters the glomerular filtrate. As a result, some glucose remains in the urine, a condition called glucosuria (gloo’-kö-soo ré-a). The most common cause of glucosuria is diabetes mellitus, in which the blood glucose level may rise far above normal because insulin activity is deficient. Rare genetic mutations in the renal Na⁺–glucose symporter greatly reduce its $T_m$ and cause glucosuria. In these cases, glucose appears in the urine even though the blood glucose level is normal. Excessive glucose in the glomerular filtrate inhibits water reabsorption by kidney tubules. This leads to increased urinary output (polyuria), decreased blood volume, and dehydration. |}

Now that we have discussed the principles of renal transport, we will follow the filtered fluid from the proximal convoluted tubule, into the loop of Henle, on to the distal convoluted tubule, and through the collecting ducts. In each segment, we will examine where and how specific substances are reabsorbed and secreted. The filtered fluid becomes tubular fluid once it enters the proximal convoluted tubule. The composition of tubular fluid changes as it flows along the nephron tubule and through the collecting duct due to reabsorption and secretion. The fluid that drains from papillary ducts into the renal pelvis is urine.

Reabsorption and Secretion in the Proximal Convoluted Tubule

The largest amount of solute and water reabsorption from filtered fluid occurs in the proximal convoluted tubules, which reabsorb 65% of the filtered water, Na⁺, and K⁺; 100% of most filtered organic solutes such as glucose and amino acids; 50% of the filtered Cl⁻; 80–90% of the filtered HCO₃⁻; 50% of the filtered urea; and a variable amount of the filtered Ca²⁺, Mg²⁺, and HPO₄²⁻ (phosphate). In addition, proximal convoluted tubules secrete a variable amount of H⁺ ions, ammonium ions (NH₄⁺), and urea.

Most solute reabsorption in the proximal convoluted tubule (PCT) involves Na⁺. Na⁺ transport occurs via symport and antiport mechanisms in the proximal convoluted tubule. Normally, filtered glucose, amino acids, lactic acid, water-soluble vitamins, and other nutrients are not lost in the urine. Rather, they are completely reabsorbed in the first half of the proximal convoluted tubule by several types of Na⁺ symporters located in the apical membrane. Figure 26.12 depicts the operation of one such symporter, the Na⁺–glucose symporter in the apical membrane of a cell in the PCT. Two Na⁺ and a molecule of glucose attach
to the symporter protein, which carries them from the tubular fluid into the tubule cell. The glucose molecules then exit the basolateral membrane via facilitated diffusion and they diffuse into peritubular capillaries. Other Na\textsuperscript{+}/H\textsuperscript{+} symporters in the PCT reclaim filtered HPO\textsubscript{4}\textsuperscript{2-} (phosphate) and SO\textsubscript{4}\textsuperscript{2-} (sulfate) ions, all amino acids, and lactic acid in a similar way.

In another secondary active transport process, the Na\textsuperscript{+}/H\textsuperscript{+} antiporters carry filtered Na\textsuperscript{+} down its concentration gradient into a PCT cell as H\textsuperscript{+} is moved from the cytosol into the lumen (Figure 26.13a), causing Na\textsuperscript{+} to be reabsorbed into blood and H\textsuperscript{+} to be secreted into tubular fluid. PCT cells produce the H\textsuperscript{+} needed to keep the antiporters running in the following way. Carbon dioxide (CO\textsubscript{2}) diffuses from peritubular blood or tubular fluid or is produced by metabolic reactions within the cells. As also occurs in red blood cells (see Figure 23.23 on page 904),

**Figure 26.12** Reabsorption of glucose by Na\textsuperscript{+}-glucose symporters in cells of the proximal convoluted tubule (PCT).

**Figure 26.13** Actions of Na\textsuperscript{+}/H\textsuperscript{+} antiporters in proximal convoluted tubule cells. (a) Reabsorption of sodium ions (Na\textsuperscript{+}) and secretion of hydrogen ions (H\textsuperscript{+}) via secondary active transport through the apical membrane; (b) reabsorption of bicarbonate ions (HCO\textsubscript{3}\textsuperscript{-}) via facilitated diffusion through the basolateral membrane.

**Which step in Na\textsuperscript{+} movement in part (a) is promoted by the electrochemical gradient?**

**Figure 26.13a** Na\textsuperscript{+}/H\textsuperscript{+} antiporters promote transcellular reabsorption of Na\textsuperscript{+} and secretion of H\textsuperscript{+}.

**Figure 26.13b** HCO\textsubscript{3}\textsuperscript{-} reabsorption.
the enzyme carbonic anhydrase (CA) catalyzes the reaction of CO₂ with water (H₂O) to form carbonic acid (H₂CO₃), which then dissociates into H⁺ and HCO₃⁻:

\[
\text{Carbonic anhydrase} \\
\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{CO}_3 \rightarrow \text{H}^+ + \text{HCO}_3^- 
\]

Most of the HCO₃⁻ in filtered fluid is reabsorbed in proximal convoluted tubules, thereby safeguarding the body’s supply of an important buffer (Figure 26.13b). After H⁺ is secreted into the fluid within the lumen of the proximal convoluted tubule, it reacts with filtered HCO₃⁻ to form H₂CO₃, which readily dissociates into CO₂ and H₂O. Carbon dioxide then diffuses into the tubule cells and joins with H₂O to form H₂CO₃, which dissociates into H⁺ and HCO₃⁻. As the level of HCO₃⁻ rises in the cytosol, it exits via facilitated diffusion transporters in the basolateral membrane and diffuses into the blood with Na⁺. Thus, for every H⁺ secreted into the tubular fluid of the proximal convoluted tubule, one HCO₃⁻ and one Na⁺ are reabsorbed.

Solute reabsorption in proximal convoluted tubules promotes osmosis of water. Each reabsorbed solute increases the osmolarity, first inside the tubule cell, then in interstitial fluid, and finally in the blood. Water thus moves rapidly from the tubular fluid, via both the paracellular and transcellular routes, into the peritubular capillaries and restores osmotic balance (Figure 26.14). In other words, reabsorption of the solutes creates an osmotic gradient that promotes the reabsorption of water via osmosis. Cells lining the proximal convoluted tubule and the descending limb of the loop of Henle are especially permeable to water because they have many molecules of aquaporin-1. This integral protein in the plasma membrane is a water channel that greatly increases the rate of water movement across the apical and basolateral membranes.

As water leaves the tubular fluid, the concentrations of the remaining filtered solutes increase. In the second half of the PCT, electrochemical gradients for Cl⁻, K⁺, Ca²⁺, Mg²⁺, and urea promote their passive diffusion into peritubular capillaries via both paracellular and transcellular routes. Among these ions, Cl⁻ is present in the highest concentration. Diffusion of negatively charged Cl⁻ into interstitial fluid via the paracellular route makes the interstitial fluid electrically more negative than the tubular fluid. This negativity promotes passive paracellular reabsorption of cations, such as K⁺, Ca²⁺, and Mg²⁺.

Ammonia (NH₃) is a poisonous waste product derived from the deamination (removal of an amino group) of various amino acids, a reaction that occurs mainly in hepatocytes (liver cells). Hepatocytes convert most of this ammonia to urea, a less-toxic compound. Although tiny amounts of urea and ammonia are present in sweat, most excretion of these nitrogen-containing waste products occurs via the urine. Urea and ammonia in blood are both filtered at the glomerulus and secreted by proximal convoluted tubule cells into the tubular fluid.

Proximal convoluted tubule cells can produce additional NH₃ by deaminating the amino acid glutamine in a reaction that also generates HCO₃⁻. The NH₃ quickly binds H⁺ to become an ammonium ion (NH₄⁺), which can substitute for H⁺/H⁺ antiporters in the apical membrane and be secreted into the tubular fluid. The HCO₃⁻ generated in this reaction moves through the basolateral membrane and then diffuses into the bloodstream, providing additional buffers in blood plasma.

**Reabsorption in the Loop of Henle**

Because all of the proximal convoluted tubules reabsorb about 65% of the filtered water (about 80 mL/min), fluid enters the next part of the nephron, the loop of Henle, at a rate of 40–45 mL/min. The chemical composition of the tubular fluid now is quite different from that of glomerular filtrate because glucose, amino acids, and other nutrients are no longer present. The osmolality of the tubular fluid is still close to the osmolality of blood, however, because reabsorption of water by osmosis keeps pace with reabsorption of solutes all along the proximal convoluted tubule.

The loop of Henle reabsorbs about 15% of the filtered water; 20–30% of the filtered Na⁺ and K⁺; 35% of the filtered Cl⁻; 10–20% of the filtered HCO₃⁻; and a variable amount of the filtered Ca²⁺ and Mg²⁺. Here, for the first time, reabsorption of water via osmosis is not automatically coupled to reabsorption of filtered solutes because part of the loop of Henle is relatively impermeable to water. The loop of Henle thus sets the stage for independent regulation of both the volume and osmolality of body fluids.
The apical membranes of cells in the thick ascending limb of the loop of Henle have **Na⁺–K⁺–2Cl⁻ symporters** that simultaneously reclaim one Na⁺, one K⁺, and two Cl⁻ from the fluid in the tubular lumen (Figure 26.15). Na⁺ that is actively transported into interstitial fluid at the base and sides of the cell diffuses into the vasa recta. Cl⁻ moves through leakage channels in the basolateral membrane into interstitial fluid and then into the vasa recta. Because many K⁺ leakage channels are present in the apical membrane, most K⁺ brought in by the symporters moves down its concentration gradient back into the tubular fluid. Thus, the main effect of the Na⁺–K⁺–2Cl⁻ symporters is reabsorption of Na⁺ and Cl⁻.

The movement of positively charged K⁺ into the tubular fluid through the apical membrane channels leaves the interstitial fluid and blood with more negative charges relative to fluid in the ascending limb of the loop of Henle. This relative negativity promotes reabsorption of cations—Na⁺, K⁺, Ca²⁺, and Mg²⁺—via the paracellular route.

Although about 15% of the filtered water is reabsorbed in the descending limb of the loop of Henle, little or no water is reabsorbed in the ascending limb. In this segment of the tubule, the apical membranes are virtually impermeable to water. Because ions but not water molecules are reabsorbed, the osmolarity of the tubular fluid decreases progressively as fluid flows toward the end of the ascending limb.

### Reabsorption in the Early Distal Convoluted Tubule

Fluid enters the distal convoluted tubules at a rate of about 25 mL/min because 80% of the filtered water has now been reabsorbed. The early or initial part of the distal convoluted tubule (DCT) reabsorbs about 10–15% of the filtered Na⁺; and 5% of the filtered Cl⁻. Reabsorption of Na⁺ and Cl⁻ occurs by means of **Na⁺–Cl⁻ symporters** in the apical membranes. Sodium-potassium pumps and Cl⁻ leakage channels in the basolateral membranes then permit reabsorption of Na⁺ and Cl⁻ into the peritubular capillaries. The early DCT also is a major site where parathyroid hormone (PTH) stimulates reabsorption of Ca²⁺. The amount of Ca²⁺ reabsorption in the early DCT varies depending on the body’s needs.

### Reabsorption and Secretion in the Late Distal Convoluted Tubule and Collecting Duct

By the time fluid reaches the end of the distal convoluted tubule, 90–95% of the filtered solutes and water have returned to the bloodstream. Recall that two different types of cells—principal cells and intercalated cells—are present at the late or terminal part of the distal convoluted tubule and throughout the collecting duct. The principal cells reabsorb Na⁺ and secrete K⁺; the intercalated cells reabsorb K⁺ and HCO₃⁻ and secrete H⁺. In the late distal convoluted tubules and collecting ducts, the amount of water and solute reabsorption and the amount of solute secretion vary depending on the body’s needs.

### Why is this process considered secondary active transport?

Does water reabsorption accompany ion reabsorption in this region of the nephron?
In contrast to earlier segments of the nephron, Na\(^+\) passes through the apical membrane of principal cells via Na\(^+\) leakage channels rather than by means of symporters or antiporters (Figure 26.16). The concentration of Na\(^+\) in the cytosol remains low, as usual, because the sodium–potassium pumps actively transport Na\(^+\) across the basolateral membranes. Then Na\(^+\) passively diffuses into the peritubular capillaries from the interstitial spaces around the tubule cells.

Normally, transcellular and paracellular reabsorption in the proximal convoluted tubule and loop of Henle return most filtered K\(^+\) to the bloodstream. To adjust for varying dietary intake of potassium and to maintain a stable level of K\(^+\) in body fluids, principal cells secrete a variable amount of K\(^+\) (Figure 26.16). Because the basolateral sodium–potassium pumps continually bring K\(^+\) into principal cells, the intracellular concentration of K\(^+\) remains high. K\(^+\) leakage channels are present in both the apical and basolateral membranes. Thus, some K\(^+\) diffuses down its concentration gradient into the tubular fluid, where the K\(^+\) concentration is very low. This secretion mechanism is the main source of K\(^+\) excreted in the urine.

**Hormonal Regulation of Tubular Reabsorption and Tubular Secretion**

Five hormones affect the extent of Na\(^+\), Cl\(^-\), Ca\(^{2+}\), and water reabsorption as well as K\(^+\) secretion by the renal tubules. These hormones include angiotensin II, aldosterone, antidiuretic hormone, atrial natriuretic peptide, and parathyroid hormone.

**Renin–Angiotensin–Aldosterone System**

When blood volume and blood pressure decrease, the walls of the afferent arterioles are stretched less, and the juxtaglomerular cells secrete the enzyme renin into the blood. Sympathetic stimulation also directly stimulates release of renin from juxtaglomerular cells. Renin clips off a 10-amino-acid peptide called angiotensin I from angiotensinogen, which is synthesized by hepatocytes. By clipping off two more amino acids, *angiotensin converting enzyme* (ACE) converts angiotensin I to *angiotensin II*, which is the active form of the hormone.

Angiotensin II affects renal physiology in three main ways:

1. It decreases the glomerular filtration rate by causing vasoconstriction of the afferent arterioles.
2. It enhances reabsorption of Na\(^+\), Cl\(^-\), and water in the proximal convoluted tubule by stimulating the activity of Na\(^+\)/H\(^+\) antiporters.
3. It stimulates the adrenal cortex to release *aldosterone*, a hormone that in turn stimulates the principal cells in the collecting ducts to reabsorb more Na\(^+\) and Cl\(^-\) and secrete more K\(^+\). The osmotic consequence of reabsorbing more Na\(^+\) and Cl\(^-\) is excreting less water, which increases blood volume.

**Antidiuretic Hormone**

Antidiuretic hormone (ADH or *vasopressin*) is released by the posterior pituitary. It regulates facultative water reabsorption by increasing the water permeability of principal cells in the last part of the distal convoluted tubule and throughout the collecting duct. In the absence of ADH, the apical membranes of principal cells have a very low permeability to water. Within principal cells are tiny vesicles containing many copies of a water channel protein known as *aquaporin-2*. ADH stimulates insertion of the aquaporin-2–containing vesicles into the apical membranes via exocytosis. As a result, the water permeability of the principal cell’s apical membrane increases, and water molecules move more rapidly from the tubular fluid into the cells. Because the

*ADH does not govern the previously mentioned water channel (aquaporin-1).*
Increased release of ADH

Return to homeostasis when response brings plasma osmolarity back to normal

Atrial Natriuretic Peptide

A large increase in blood volume promotes release of atrial natriuretic peptide (ANP) from the heart. Although the importance of ANP in normal regulation of tubular function is unclear, it can inhibit reabsorption of Na⁺ and water in the proximal convoluted tubule and collecting duct. ANP also suppresses the secretion of aldosterone and ADH. These effects increase the excretion of Na⁺ in urine (natriuresis) and increase urine output (diuresis), which decreases blood volume and blood pressure.

Parathyroid Hormone

A lower-than-normal level of Ca²⁺ in the blood stimulates the parathyroid glands to release parathyroid hormone (PTH). PTH in turn stimulates cells in the early distal convoluted tubules to reabsorb more Ca²⁺ into the blood. PTH also inhibits HPO₄⁻²⁻ (phosphate) reabsorption in proximal convoluted tubules, thereby promoting phosphate excretion.

Table 26.4 summarizes hormonal regulation of tubular reabsorption and tubular secretion.

CHECKPOINT

11. Diagram the reabsorption of substances via the transcellular and paracellular routes. Label the apical membrane and the basolateral membrane. Where are the sodium–potassium pumps located?

12. Describe two mechanisms in the PCT, one in the LOH, one in the DCT, and one in the collecting duct for reabsorption of Na⁺. What other solutes are reabsorbed or secreted with Na⁺ in each mechanism?

13. How do intercalated cells secrete hydrogen ions?

14. Graph the percentages of filtered water and filtered Na⁺ that are reabsorbed in the PCT, LOH, DCT, and collecting duct. Indicate which hormones, if any, regulate reabsorption in each segment.

In addition to ADH, which other hormones contribute to the regulation of water reabsorption?

**PRODUCTION OF DILUTE AND CONCENTRATED URINE**

**Objective**
- Describe how the renal tubule and collecting ducts produce dilute and concentrated urine.

Even though your fluid intake can be highly variable, the total volume of fluid in your body normally remains stable. Homeostasis of body fluid volume depends in large part on the ability of the kidneys to regulate the rate of water loss in urine. Normally functioning kidneys produce a large volume of dilute urine when fluid intake is high, and a small volume of concentrated urine when fluid intake is low or fluid loss is large. ADH controls whether dilute urine or concentrated urine is formed. In the absence of ADH, urine is very dilute. However, a high level of ADH stimulates reabsorption of more water into blood, producing a concentrated urine.

**Formation of Dilute Urine**

Glomerular filtrate has the same ratio of water and solute particles as blood; its osmolarity is about 300 mOsm/liter. As previously noted, fluid leaving the proximal convoluted tubule is still isotonic to plasma. When dilute urine is being formed (Figure 26.18), the osmolarity of the fluid in the tubular lumen increases as it flows down the descending limb of the loop of Henle, decreases as it flows up the ascending limb, and decreases still more as it flows through the rest of the nephron and collecting duct. These changes in osmolarity result from the following conditions along the path of tubular fluid:

1. Because the osmolarity of the interstitial fluid of the renal medulla becomes progressively greater, more and more water is reabsorbed by osmosis as tubular fluid flows along the descending limb toward the tip of the loop. (The source of this medullary osmotic gradient is explained shortly.) As a result, the fluid remaining in the lumen becomes progressively more concentrated.

2. Cells lining the thick ascending limb of the loop have symporters that actively reabsorb Na⁺, K⁺, and Cl⁻ from the tubular fluid (see Figure 26.15). The ions pass from the tubular fluid into thick ascending limb cells, then into interstitial fluid, and finally some diffuse into the blood inside the vasa recta.

3. Although solutes are being reabsorbed in the thick ascending limb, the water permeability of this portion of the nephron is always quite low, so water cannot follow by osmosis. As solutes—but not water molecules—are leaving the tubular fluid, its osmolarity drops to about 150 mOsm/liter. The fluid entering the distal convoluted tubule is thus more dilute than plasma.

4. While the fluid continues flowing along the distal convoluted tubule, additional solutes but only a few water molecules
are reabsorbed. The early distal convoluted tubule cells are not very permeable to water and are not regulated by ADH.

5. Finally, the principal cells of the late distal convoluted tubules and collecting ducts are impermeable to water when the ADH level is very low. Thus, tubular fluid becomes progressively more dilute as it flows onward. By the time the tubular fluid drains into the renal pelvis, its concentration can be as low as 65–70 mOsm/liter. This is four times more dilute than blood plasma or glomerular filtrate.

**Figure 26.18 Formation of dilute urine.** Numbers indicate osmolarity in milliosmoles per liter (mOsm/liter). Heavy brown lines in the ascending limb of the loop of Henle and in the distal convoluted tubule indicate impermeability to water; heavy blue lines indicate the last part of the distal convoluted tubule and the collecting duct, which are impermeable to water in the absence of ADH; light blue areas around the nephron represent interstitial fluid. When ADH is absent, the osmolarity of urine can be as low as 65 mOsm/liter.

When ADH level is low, urine is dilute and has an osmolarity less than the osmolarity of blood.

**Formation of Concentrated Urine**

When water intake is low or water loss is high (such as during heavy sweating), the kidneys must conserve water while still eliminating wastes and excess ions. Under the influence of ADH, the kidneys produce a small volume of highly concentrated urine. Urine can be four times more concentrated (up to 1200 mOsm/liter) than blood plasma or glomerular filtrate.

The ability of ADH to cause excretion of concentrated urine depends on the presence of an osmotic gradient of solutes in the interstitial fluid of the renal medulla. Notice in Figure 26.19 on page 1044 that the solute concentration of the interstitial fluid in the kidney increases from about 300 mOsm/liter in the renal cortex to about 1200 mOsm/liter deep in the renal medulla. The three major solutes that contribute to this high osmolarity are Na\(^+\), Cl\(^-\), and urea. Two main factors contribute to building and maintaining this osmotic gradient: (1) differences in solute and water permeability and reabsorption in different sections of the long loops of Henle and the collecting ducts, and (2) the countercurrent flow of fluid through tube-shaped structures in the renal medulla. Countercurrent flow refers to the flow of fluid in opposite directions. This occurs when fluid flowing in one tube runs counter (opposite) to fluid flowing in a nearby parallel tube. Examples of countercurrent flow include the flow of tubular fluid through the descending and ascending limbs of the loop of Henle and the flow of blood through the ascending and descending parts of the vasa recta. Two types of countercurrent mechanisms exist in the kidneys: countercurrent multiplication and countercurrent exchange.

**Countercurrent Multiplication**

Countercurrent multiplication is the process by which a progressively increasing osmotic gradient is formed in the interstitial fluid of the renal medulla as a result of countercurrent flow. Countercurrent multiplication involves the long loops of Henle of juxtamedullary nephrons. Note in Figure 26.19a that the descending limb of the loop of Henle carries tubular fluid from the renal cortex deep into the medulla, and the ascending limb carries it in the opposite direction. Since countercurrent flow through the descending and ascending limbs of the long loop of Henle establishes the osmotic gradient in the renal medulla, the long loop of Henle is said to function as a countercurrent multiplier. The kidneys use this osmotic gradient to excrete concentrated urine.

Production of concentrated urine by the kidneys occurs in the following way (Figure 26.19):

1. **Symporters in thick ascending limb cells of the loop of Henle cause a buildup of Na\(^+\) and Cl\(^-\) in the renal medulla.** In the thick ascending limb of the loop of Henle, the Na\(^+\)–K\(^+\)–2Cl\(^-\) symporters reabsorb Na\(^+\) and Cl\(^-\) from the tubular fluid (Figure 26.19a). Water is not reabsorbed in this segment, however, because the cells are impermeable to water. As a result, there is a buildup of Na\(^+\) and Cl\(^-\) ions in the interstitial fluid of the medulla.
Countercurrent flow through the descending and ascending limbs of the loop of Henle establishes an osmotic gradient in the renal medulla. Since tubular fluid constantly moves from the descending limb to the thick ascending limb of the loop of Henle, the thick ascending limb is constantly reabsorbing Na\(^+\) and Cl\(^-\). Consequently, the reabsorbed Na\(^+\) and Cl\(^-\) become increasingly concentrated in the interstitial fluid of the medulla, which results in the formation of an osmotic gradient that ranges from 300 mOsm/liter in the outer medulla to 1200 mOsm/liter deep in the inner medulla. The descending limb of the loop of Henle is very permeable to water but impermeable to solutes except urea. Because the

Figure 26.19 Mechanism of urine concentration in long-loop juxtamedullary nephrons. The green line indicates the presence of Na\(^+\)-K\(^-\)-2Cl\(^-\) symporters that simultaneously reabsorb these ions into the interstitial fluid of the renal medulla; this portion of the nephron is also relatively impermeable to water and urea. All concentrations are in milliosmoles per liter (mOsm/liter).

The formation of concentrated urine depends on high concentrations of solutes in interstitial fluid in the renal medulla.
osmolarity of the interstitial fluid outside the descending limb is higher than the tubular fluid within it, water moves out of the descending limb via osmosis. This causes the osmolarity of the tubular fluid to increase. As the fluid continues along the descending limb, its osmolarity increases even more: At the hairpin turn of the loop, the osmolarity can be as high as 1200 mOsm/liter in juxtedudillary nephrons. As you have already learned, the ascending limb of the loop is impermeable to water, but its symporters reabsorb Na⁺ and Cl⁻ from the tubular fluid into the interstitial fluid of the renal medulla, so the osmolarity of the tubular fluid progressively decreases as it flows through the ascending limb. At the junction of the medulla and cortex, the osmolarity of the tubular fluid has fallen to about 100 mOsm/liter. Overall, tubular fluid becomes progressively more concentrated as it flows along the descending limb and progressively more dilute as it moves along the ascending limb.

3 **Cells in the collecting ducts reabsorb more water and urea.** When ADH increases the water permeability of the principal cells, water quickly moves via osmosis out of the collecting duct tubular fluid, into the interstitial fluid of the inner medulla, and then into the vasa recta. With loss of water, the urea left behind in the tubular fluid of the collecting duct becomes increasingly concentrated. Because duct cells deep in the medulla are permeable to it, urea diffuses from the fluid in the duct into the interstitial fluid of the medulla.

4 **Urea recycling causes a buildup of urea in the renal medulla.** As urea accumulates in the interstitial fluid, some of it diffuses into the tubular fluid in the descending and thin ascending limbs of the long loops of Henle, which also are permeable to urea (Figure 26.19a). However, while the fluid flows through the thick ascending limb, distal convoluted tubule, and cortical portion of the collecting duct, urea remains in the lumen because cells in these segments are impermeable to it. As fluid flows along the collecting ducts, water reabsorption continues via osmosis because ADH is present. This water reabsorption further increases the concentration of urea in the tubular fluid, more urea diffuses into the interstitial fluid of the inner renal medulla, and the cycle repeats. The constant transfer of urea between segments of the renal tubule and the interstitial fluid of the medulla is termed **urea recycling.** In this way, reabsorption of water from the tubular fluid of the ducts promotes the buildup of urea in the interstitial fluid of the renal medulla, which in turn promotes water reabsorption. The solutes left behind in the lumen thus become very concentrated, and a small volume of concentrated urine is excreted.

**Countercurrent Exchange**

**Countercurrent exchange** is the process by which solutes and water are passively exchanged between the blood of the vasa recta and interstitial fluid of the renal medulla as a result of countercurrent flow. Note in Figure 26.19b that the vasa recta also consists of descending and ascending limbs that are parallel to each other and to the loop of Henle. Just as tubular fluid flows in opposite directions in the loop of Henle, blood flows in opposite directions in the ascending and descending parts of the vasa recta. Since countercurrent flow between the descending and ascending limbs of the vasa recta allows for exchange of solutes and water between the blood and interstitial fluid of the renal medulla, the vasa recta is said to function as a **countercurrent exchanger.**

Blood entering the vasa recta has an osmolarity of about 300 mOsm/liter. As it flows along the descending part into the renal medulla, where the interstitial fluid becomes increasingly concentrated, Na⁺, Cl⁻, and urea diffuse from interstitial fluid into the blood and water diffuses from the blood into the interstitial fluid. But after its osmolarity increases, the blood flows into the ascending part of the vasa recta. Here blood flows through a region where the interstitial fluid becomes increasingly less concentrated. As a result Na⁺, Cl⁻, and urea diffuse from the blood back into interstitial fluid, and water diffuses from interstitial fluid back into the vasa recta. The osmolarity of blood leaving the vasa recta is only slightly higher than the osmolarity of blood entering the vasa recta. Thus, the vasa recta provides oxygen and nutrients to the renal medulla without washing out or diminishing the osmotic gradient. The long loop of Henle establishes the osmotic gradient in the renal medulla by countercurrent multiplication, but the vasa recta maintains the osmotic gradient in the renal medulla by countercurrent exchange.

**Check-up**

15. How do symporters in the ascending limb of the loop of Henle and principal cells in the collecting duct contribute to the formation of concentrated urine?

16. How does ADH regulate facultative water reabsorption?

17. What is the countercurrent mechanism? Why is it important?
**Figure 26.20** Summary of filtration, reabsorption, and secretion in the nephron and collecting duct.

**RENAL CORPUSCLE**

Glomerular filtration rate:
105–125 mL/min of fluid that is isotonic to blood

**Filtered substances:** water and all solutes present in blood (except proteins) including ions, glucose, amino acids, creatinine, uric acid

**EARLY DISTAL CONVOLUTED TUBULE**

Reabsorption (into blood) of:
Water 5–9% (insertion of water channels stimulated by ADH) Na⁺ 1–4% (sodium-potassium pumps, sodium channels stimulated by aldosterone) Urea variable (recycling to loop of Henle)

**LATE DISTAL CONVOLUTED TUBULE AND COLLECTING DUCT**

Reabsorption (into blood) of:
Water 5–9% (insertion of water channels stimulated by ADH) Na⁺ 1–4% (sodium-potassium pumps and sodium channels stimulated by aldosterone) HCO₃⁻ variable amount, depends on H⁺ secretion (antiporters) Urea variable (recycling to loop of Henle)

**Urine**

HCO₃⁻ variable amount, depends on H⁺ secretion (antiporters)

**In which segments of the nephron and collecting duct does secretion occur?**
The following equation is used to calculate clearance:

\[ S = \frac{U \times V}{P} \]

where:
- \( S \) is the renal plasma clearance of a substance.
- \( U \) is the amount of a substance excreted in the urine per unit of time.
- \( V \) is the volume of urine produced per unit of time.
- \( P \) is the plasma concentration of the substance.

**EVALUATION OF KIDNEY FUNCTION**

**OBJECTIVES**

- Define urinalysis and describe its importance.
- Define renal plasma clearance and describe its importance.

Routine assessment of kidney function involves evaluating both the quantity and quality of urine and the levels of wastes in the blood.

**Urinalysis**

An analysis of the volume and physical, chemical, and microscopic properties of urine, called a urinalysis, reveals much about the state of the body. Table 26.5 summarizes the major characteristics of normal urine. The volume of urine eliminated per day in a normal adult is 1–2 liters (about 1–2 qt). Fluid intake, blood pressure, blood osmolality, diet, body temperature, diuretics, mental state, and general health influence urine volume. For example, low blood pressure triggers the renin–angiotensin–aldosterone pathway. Aldosterone increases reabsorption of water and salts in the renal tubules and decreases urine volume. By contrast, when blood osmolality decreases—for example, after drinking a large volume of water—secretion of ADH is inhibited and a larger volume of urine is excreted.

Water accounts for about 95% of the total volume of urine. The remaining 5% consists of electrolytes, solutes derived from cellular metabolism, and exogenous substances such as drugs. Normal urine is virtually protein-free. Typical solutes normally present in urine include filtered and secreted electrolytes that are not reabsorbed, urea (from breakdown of proteins), creatinine (from breakdown of creatine phosphate in muscle fibers), uric acid (from breakdown of nucleic acids), urobilinogen (from breakdown of hemoglobin), and small quantities of other substances, such as fatty acids, pigments, enzymes, and hormones.

If disease alters body metabolism or kidney function, traces of substances not normally present may appear in the urine, or normal constituents may appear in abnormal amounts. Table 26.6 lists several abnormal constituents in urine that may be detected as part of a urinalysis. Normal values of urine components and the clinical implications of deviations from normal are listed in Appendix D.

**Blood Tests**

Two blood-screening tests can provide information about kidney function. One is the blood urea nitrogen (BUN) test, which measures the blood nitrogen that is part of the urea resulting from catabolism and deamination of amino acids. When glomerular filtration rate decreases severely, as may occur with renal disease or obstruction of the urinary tract, BUN rises steeply. One strategy in treating such patients is to minimize their protein intake, thereby reducing the rate of urea production.

Another test often used to evaluate kidney function is measurement of plasma creatinine, which results from catabolism of creatine phosphate in skeletal muscle. Normally, the blood creatinine level remains steady because the rate of creatinine excretion in the urine equals its discharge from muscle. A creatinine level above 1.5 mg/dL (135 mmol/liter) usually is an indication of poor renal function. Normal values for selected blood tests are listed in Appendix C along with situations that may cause the values to increase or decrease.

**Renal Plasma Clearance**

Even more useful than BUN and blood creatinine values in the diagnosis of kidney problems is an evaluation of how effectively the kidneys are removing a given substance from blood plasma. Renal plasma clearance is the volume of blood that is “cleaned” or cleared of a substance per unit of time, usually expressed in units of milliliters per minute. High renal plasma clearance indicates efficient excretion of a substance in the urine; low clearance indicates inefficient excretion. For example, the clearance of glucose normally is zero because it is completely reabsorbed (see Table 26.3); therefore, glucose is not excreted at all. Knowing a drug’s clearance is essential for determining the correct dosage. If clearance is high (one example is penicillin), then the dosage must also be high, and the drug must be given several times a day to maintain an adequate therapeutic level in the blood.

The following equation is used to calculate clearance:

\[ S = \frac{U \times V}{P} \]
where $U$ and $P$ are the concentrations of the substance in urine and plasma, respectively (both expressed in the same units, such as mg/mL), and $V$ is the urine flow rate in mL/min.

The clearance of a solute depends on the three basic processes of a nephron: glomerular filtration, tubular reabsorption, and tubular secretion. Consider a substance that is filtered in the glomerulus. Its clearance typically is less than the GFR, but neither reabsorbed nor secreted. Its clearance equals the renal plasma flow, $\frac{V}{GFR}$, where $V$ is the urine flow rate in mL/min.

TABLE 26.6

<table>
<thead>
<tr>
<th>ABNORMAL CONSTITUENT</th>
<th>COMMENTS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Albumin</td>
<td>A normal constituent of plasma, it usually appears in only very small amounts in urine because it is too large to pass through capillary fenestrations. The presence of excessive albumin in the urine—albuminuria (al’-bü-mi-NOO-rë-a)—indicates an increase in the permeability of filtration membranes due to injury or disease, increased blood pressure, or irritation of kidney cells by substances such as bacterial toxins, ether, or heavy metals.</td>
</tr>
<tr>
<td>Glucose</td>
<td>The presence of glucose in the urine is called glucosuria (gloo-kö-SÖO-rë-a) and usually indicates diabetes mellitus. Occasionally it may be caused by stress, which can cause excessive amounts of epinephrine to be secreted. Epinephrine stimulates the breakdown of glycogen and liberation of glucose from the liver.</td>
</tr>
<tr>
<td>Red blood cells</td>
<td>The presence of red blood cells in the urine is called hematuria (hēm-a-TOO-rë-a) and generally indicates a pathological condition. One cause is acute inflammation of the urinary organs as a result of disease or irritation from kidney stones. Other causes include tumors, trauma, and kidney disease, or possible contamination of the sample by menstrual blood.</td>
</tr>
<tr>
<td>Ketone bodies</td>
<td>High levels of ketone bodies in the urine, called ketonuria (kē-tō-NOO-rë-a), may indicate diabetes mellitus, anorexia, starvation, or simply too little carbohydrate in the diet.</td>
</tr>
<tr>
<td>Bilirubin</td>
<td>When red blood cells are destroyed by macrophages, the globin portion of hemoglobin is split off and the heme is converted to biliverdin. Most of the biliverdin is converted to bilirubin, which gives bile its major pigmentation. An above-normal level of bilirubin in urine is called bilirubinuria (bi’lē-ROO-bi-NOO-rë-a).</td>
</tr>
<tr>
<td>Urobilinogen</td>
<td>The presence of urobilinogen (breakdown product of hemoglobin) in urine is called urobilinogenuria (û-ro-bi-lë-nö-JÖO-rë-a). Trace amounts are normal, but elevated urobilinogen may be due to hemolytic or pernicious anemia, infectious hepatitis, biliary obstruction, jaundice, cirrhosis, congestive heart failure, or infectious mononucleosis.</td>
</tr>
<tr>
<td>Casts</td>
<td>Casts are tiny masses of material that have hardened and assumed the shape of the lumen of the tubule in which they formed. They are then flushed out of the tubule when filtrate builds up behind them. Casts are named after the cells or substances that compose them or based on their appearance. For example, there are white blood cell casts, red blood cell casts, and epithelial cell casts that contain cells from the walls of the tubules.</td>
</tr>
<tr>
<td>Microbes</td>
<td>The number and type of bacteria vary with specific infections in the urinary tract. One of the most common is E. coli. The most frequent protozoan seen is Trichomonas vaginalis, a cause of vaginitis. The most frequent fungus to appear in urine is the yeast Candida albicans, a cause of vaginitis.</td>
</tr>
</tbody>
</table>

where $U$ and $P$ are the concentrations of the substance in urine and plasma, respectively (both expressed in the same units, such as mg/mL), and $V$ is the urine flow rate in mL/min.

The clearance of a solute depends on the three basic processes of a nephron: glomerular filtration, tubular reabsorption, and tubular secretion. Consider a substance that is filtered in the glomerulus. Its clearance typically is less than the GFR, but neither reabsorbed nor secreted. Its clearance equals the renal plasma flow, $\frac{V}{GFR}$, where $V$ is the urine flow rate in mL/min.

The clearance of the organic anion para-aminohippuric acid (PAH) is also of clinical importance. After PAH is administered intravenously, it is filtered and secreted in a single pass through the kidneys. Thus, the clearance of PAH is used to measure renal plasma flow, the amount of plasma that passes through the kidneys in one minute. Typically, the renal plasma flow is 650 mL per minute, which is about 55% of the renal blood flow (1200 mL per minute).
CHECKPOINT
18. What are the characteristics of normal urine?
19. What chemical substances normally are present in urine?
20. How may kidney function be evaluated?
21. Why are the renal plasma clearances of glucose, urea, and creatinine different? How does each clearance compare to glomerular filtration rate?

URINE TRANSPORTATION, STORAGE, AND ELIMINATION

OBJECTIVE
• Describe the anatomy, histology, and physiology of the ureters, urinary bladder, and urethra.

From collecting ducts, urine drains through papillary ducts into the minor calyces, which join to become major calyces that unite to form the renal pelvis (see Figure 26.3). From the renal pelvis, urine first drains into the ureters and then into the urinary bladder. Urine is then discharged from the body through the single urethra (see Figure 26.1).

Ureters
Each of the two ureters (Ür-e-ters) transports urine from the renal pelvis of one kidney to the urinary bladder. Peristaltic contractions of the muscular walls of the ureters push urine toward the urinary bladder, but hydrostatic pressure and gravity also contribute. Peristaltic waves that pass from the renal pelvis to the urinary bladder vary in frequency from one to five per minute, depending on how fast urine is being formed.

The ureters are 25–30 cm (10–12 in.) long and are thick-walled, narrow tubes that vary in diameter from 1 mm to 10 mm along their course between the renal pelvis and the urinary bladder. Like the kidneys, the ureters are retroperitoneal. At the base of the urinary bladder, the ureters curve medially and pass obliquely through the wall of the posterior aspect of the urinary bladder (Figure 26.21).

Even though there is no anatomical valve at the opening of each ureter into the urinary bladder, a physiological one is quite effective. As the urinary bladder fills with urine, pressure within it compresses the oblique openings into the ureters and prevents the backflow of urine. When this physiological valve is not operating properly, it is possible for microbes to travel up the ureters from the urinary bladder to infect one or both kidneys.

What is a lack of voluntary control over micturition called?
Three layers of tissue form the wall of the ureters. The deepest coat, the mucosa, is a mucous membrane with transitional epithelium (see Table 4.11 on page 119) and an underlying lamina propria of areolar connective tissue with considerable collagen, elastic fibers, and lymphatic tissue. Transitional epithelium is able to stretch—a marked advantage for any organ that must accommodate a variable volume of fluid. Mucus secreted by the goblet cells of the mucosa prevents the cells from coming in contact with urine, the solute concentration and pH of which may differ drastically from the cytosol of cells that form the wall of the ureters.

Throughout most of the length of the ureters, the intermediate coat, the muscularis, is composed of inner longitudinal and outer circular layers of smooth muscle fibers. This arrangement is opposite to that of the gastrointestinal tract, which contains inner circular and outer longitudinal layers. The muscularis of the distal third of the ureters also contains an outer layer of longitudinal muscle fibers. Thus, the muscularis in the distal third of the ureters may differ drastically from the cytosol of cells that form the wall of the ureters.

The superficial coat of the ureters is the adventitia, a layer of areolar connective tissue containing blood vessels, lymphatic vessels, and nerves that serve the muscularis and mucosa. The adventitia blends in with surrounding connective tissue and anchors the ureters in place.

### Urinary Bladder

The urinary bladder is a hollow, distensible muscular organ situated in the pelvic cavity posterior to the pubic symphysis. In males, it is directly anterior to the rectum; in females, it is anterior to the vagina and inferior to the uterus (see Figure 26.22). Folds of the peritoneum hold the urinary bladder in position. When slightly distended due to the accumulation of urine, the urinary bladder is spherical. When it is empty, it collapses. As urine volume increases, it becomes pear-shaped and rises into the abdominal cavity. Urinary bladder capacity averages 700–800 mL. It is smaller in females because the uterus occupies the space just superior to the urinary bladder.

### Anatomy and Histology of the Urinary Bladder

In the floor of the urinary bladder is a small triangular area called the trigone ( TRI -gōn = triangle). The two posterior corners of the trigone contain the two ureteral openings; the opening into the urethra, the internal urethral orifice, lies in the anterior corner (Figure 26.21). Because its mucosa is firmly bound to the muscularis, the trigone has a smooth appearance.

Three coats make up the wall of the urinary bladder. The deepest is the mucosa, a mucous membrane composed of transitional epithelium and an underlying lamina propria similar to that of the ureters. Rugae (the folds in the mucosa) are also present to permit expansion of the urinary bladder. Surrounding the mucosa is the intermediate muscularis, also called the detrusor muscle ( de -TROO -ser = to push down), which consists of three layers of smooth muscle fibers: the inner longitudinal, middle circular, and outer longitudinal layers. Around the opening to the urethra the circular fibers form an internal urethral sphincter; inferior to it is the external urethral sphincter, which is composed of skeletal muscle and is a modification of the deep muscles of the perineum (see Figure 11.12 on page 367). The most superficial coat of the urinary bladder on the posterior and inferior surfaces is the adventitia, a layer of areolar connective tissue that is continuous with that of the ureters. Over the superior surface of the urinary bladder is the serosa, a layer of visceral peritoneum.

### The Micturition Reflex

Discharge of urine from the urinary bladder, called micturition (mi k`-too-RISH -un; mictur- = urinate), is also known as urination or voiding. Micturition occurs via a combination of involuntary and voluntary muscle contractions. When the volume of urine in the urinary bladder exceeds 200–400 mL, pressure within the bladder increases considerably, and stretch receptors in its wall transmit nerve impulses into the spinal cord. These impulses propagate to the micturition center in sacral spinal cord segments S2 and S3 and trigger a spinal reflex called the micturition reflex. In this reflex arc, parasympathetic impulses from the micturition center propagate to the urinary bladder wall and internal urethral sphincter. The nerve impulses cause contraction of the detrusor muscle and relaxation of the internal urethral sphincter muscle. Simultaneously, the micturition center inhibits somatic motor neurons that innervate skeletal muscle in the external urethral sphincter. Upon contraction of the urinary bladder wall and relaxation of the sphincters, urination takes place. Urinary bladder filling causes a sensation of fullness that initiates a conscious desire to urinate before the micturition reflex actually occurs. Although emptying of the urinary bladder is a reflex, in early childhood we learn to initiate it and stop it voluntarily. Through learned control of the external urethral sphincter muscle and certain muscles of the pelvic floor, the cerebral cortex can initiate micturition or delay its occurrence for a limited period.

### Clinical Connection: Cystoscopy

Cystoscopy (sis-TOS-kō -pē; cysto- = bladder; -skopy = to examine) is a very important procedure for direct examination of the mucosa of the urethra and urinary bladder and prostate in males. In the procedure, a cystoscope (a flexible narrow tube with a light) is inserted into the urethra to examine the structures through which it passes. With special attachments, tissue samples can be removed for examination (biopsy) and small stones can be removed. Cystoscopy is useful for evaluating urinary bladder problems such as cancer and infections. It can also evaluate the degree of obstruction resulting from an enlarged prostate.

### Urethra

The urethra (ū-RĒ -thra) is a small tube leading from the internal urethral orifice in the floor of the urinary bladder to the exterior of the body. In both males and females, the urethra is the terminal portion of the urinary system and the passageway
Figure 26.22  Comparison between female and male urethras.

The female urethra is about 4 cm (1.5 in.) in length, while the male urethra is about 20 cm (8 in.) in length.

What are the three subdivisions of the male urethra?
for discharging urine from the body. In males, it discharges semen (fluid that contains sperm) as well.

In females, the urethra lies directly posterior to the pubic symphysis, is directed obliquely, inferiorly, and anteriorly, and has a length of 4 cm (1.5 in.) (Figure 26.22a). The opening of the urethra to the exterior, the external urethral orifice, is located between the clitoris and the vaginal opening (see Figure 28.11a on page 1096). The wall of the female urethra consists of a deep mucosa and a superficial muscularis. The mucosa is a mucous membrane composed of epithelium and lamina propria (areolar connective tissue with elastic fibers and a plexus of veins). The muscularis consists of circularly arranged smooth muscle fibers and is continuous with that of the urinary bladder. Near the urinary bladder, the mucosa contains transitional epithelium that is continuous with that of the urinary bladder: near the external urethral orifice, the epithelium is nonkeratinized stratified squamous epithelium. Between these areas, the mucosa contains stratified columnar or pseudostratified columnar epithelium.

In males, the urethra also extends from the internal urethral orifice to the exterior, but its length and passage through the body are considerably different than in females (Figure 26.22b). The male urethra first passes through the prostate, then through the deep muscles of the perineum, and finally through the penis, a distance of about 20 cm (8 in.).

The male urethra, which also consists of a deep mucosa and a superficial muscularis, is subdivided into three anatomical regions: (1) The prostatic urethra passes through the prostate. (2) The membranous (intermediate) urethra, the shortest portion, passes through the deep muscles of the perineum. (3) The spongy urethra, the longest portion, passes through the penis. The epithelium of the prostatic urethra is continuous with that of the urinary bladder and consists of transitional epithelium that becomes stratified columnar or pseudostratified columnar epithelium more distally. The mucosa of the membranous urethra contains stratified columnar or pseudostratified columnar epithelium. The epithelium of the spongy urethra is stratified columnar or pseudostratified columnar epithelium, except near the external urethral orifice. There it is nonkeratinized stratified squamous epithelium. The lamina propria of the male urethra is areolar connective tissue with elastic fibers and a plexus of veins. The muscularis of the prostatic urethra is composed of mostly circular smooth muscle fibers superficial to the lamina propria; these circular fibers help form the internal urethral sphincter of the urinary bladder. The muscularis of the membranous urethra consists of circularly arranged skeletal muscle fibers of the deep muscles of the perineum that help form the external urethral sphincter of the urinary bladder.

Several glands and other structures associated with reproduction (described in detail in Chapter 28) deliver their contents into the male urethra. The prostatic urethra receives secretions that contain sperm, neutralize the acidity of the female reproductive tract, and contribute to sperm motility and viability. The spongy urethra receives an alkaline substance before ejaculation that neutralizes the acidity of the urethra, and mucus, which lubricates the end of the penis during sexual arousal. The entire urethra, but especially the spongy urethra, receives mucus during sexual arousal or ejaculation.

**CLINICAL CONNECTION**  **Urinary Incontinence**

A lack of voluntary control over micturition is called urinary incontinence. In infants and children under 2–3 years old, incontinence is normal because neurons to the external urethral sphincter muscle are not completely developed; voiding occurs whenever the urinary bladder is sufficiently distended to stimulate the micturition reflex. Urinary incontinence also occurs in adults. There are four types of urinary incontinence—stress, urge, overflow, and functional. Stress incontinence is the most common type of incontinence in young and middle-aged females, and results from weakness of the deep muscles of the pelvic floor. As a result, any physical stress that increases abdominal pressure, such as coughing, sneezing, laughing, exercising, straining, lifting heavy objects, and pregnancy, causes leakage of urine from the urinary bladder. Urge incontinence is most common in older people and is characterized by an abrupt and intense urge to urinate followed by an involuntary loss of urine. It may be caused by irritation of the urinary bladder wall by infection or kidney stones, stroke, multiple sclerosis, spinal cord injury, or anxiety. Overflow incontinence refers to the involuntary leakage of small amounts of urine caused by some type of blockage or weak contractions of the musculature of the urinary bladder. When urine flow is blocked (for example, from an enlarged prostate or kidney stones) or the urinary bladder muscles can no longer contract, the urinary bladder becomes overfilled and the pressure inside increases until small amounts of urine dribble out. Functional incontinence is urine loss resulting from the inability to get to a toilet facility in time as a result of conditions such as stroke, severe arthritis, and Alzheimer disease. Choosing the right treatment option depends on correct diagnosis of the type of incontinence. Treatments include Kegel exercises (see page 367), urinary bladder training, medication, and possibly even surgery.

**CHECKPOINT**

22. What forces help propel urine from the renal pelvis to the urinary bladder?
23. What is micturition? How does the micturition reflex occur?
24. How do the location, length, and histology of the urethra compare in males and females?

**WASTE MANAGEMENT IN OTHER BODY SYSTEMS**

**OBJECTIVE**

- Describe the ways that body wastes are handled.

As we have seen, just one of the many functions of the urinary system is to help rid the body of some kinds of waste materials. Besides the kidneys, several other tissues, organs, and processes contribute to the temporary confinement of wastes, the transport
of waste materials for disposal, the recycling of materials, and the excretion of excess or toxic substances in the body. These waste management systems include the following:

- **Body buffers.** Buffers in body fluids bind excess hydrogen ions (H\(^+\)), thereby preventing an increase in the acidity of body fluids. Buffers, like wastebaskets, have a limited capacity; eventually the H\(^+\), like the paper in a wastebasket, must be eliminated from the body by excretion.

- **Blood.** The bloodstream provides pickup and delivery services for the transport of wastes, in much the same way that garbage trucks and sewer lines serve a community.

- **Liver.** The liver is the primary site for metabolic recycling, as occurs, for example, in the conversion of amino acids into glucose or of glucose into fatty acids. The liver also converts toxic substances into less toxic ones, such as ammonia into urea. These functions of the liver are described in Chapters 24 and 25.

- **Lungs.** With each exhalation, the lungs excrete CO\(_2\), and expel heat and a little water vapor.

- **Sweat (sudoriferous) glands.** Especially during exercise, sweat glands in the skin help eliminate excess heat, water, and CO\(_2\), plus small quantities of salts and urea as well.

- **Gastrointestinal tract.** Through defecation, the gastrointestinal tract excretes solid, undigested foods; wastes; some CO\(_2\); water; salts; and heat.

### CHECKPOINT

25. What roles do the liver and lungs play in the elimination of wastes?

### DEVELOPMENT OF THE URINARY SYSTEM

#### OBJECTIVE

- Describe the development of the urinary system.

Starting in the third week of fetal development, a portion of the mesoderm along the posterior aspect of the embryo, the intermediate mesoderm, differentiates into the kidneys. The intermediate mesoderm is located in paired elevations called urogenital ridges. Three pairs of kidneys form within the intermediate mesoderm in succession: the pronephros, the mesonephros, and the metanephros (Figure 26.23 on page 1054). Only the last pair remains as the functional kidneys of the newborn.

The first kidney to form, the pronephros (prō-NEF-rōs; pro- = before; -nephrōs = kidney), is the most superior of the three and has an associated pronephric duct. This duct empties into the cloaca, the expanded terminal part of the hindgut, which functions as a common outlet for the urinary, digestive, and reproductive ducts. The pronephros begins to degenerate during the fourth week and is completely gone by the sixth week.

The second kidney, the mesonephros (mez'-ō-NEF-rōs; meso- = middle), replaces the pronephros. The retained portion of the pronephric duct, which connects to the mesonephros, develops into the mesonephric duct. The mesonephros begins to degenerate by the sixth week and is almost gone by the eighth week.

At about the fifth week, a mesodermal outgrowth, called a ureteric bud (ū-TER-ik), develops from the distal portion of the mesonephric duct near the cloaca. The metanephros (met-a-NEF-rōs; meta- = after), or ultimate kidney, develops from the ureteric bud and metanephric mesoderm. The ureteric bud forms the collecting ducts, calyces, renal pelvis, and ureter. The metanephric mesoderm forms the nephrons of the kidneys. By the third month, the fetal kidneys begin excreting urine into the surrounding amniotic fluid; indeed, fetal urine makes up most of the amniotic fluid.

During development, the cloaca divides into a urogenital sinus, into which urinary and genital ducts empty, and a rectum that discharges into the anal canal. The urinary bladder develops from the urogenital sinus. In females, the urethra develops as a result of lengthening of the short duct that extends from the urinary bladder to the urogenital sinus. In males, the urethra is considerably longer and more complicated, but it is also derived from the urogenital sinus.

Although the metanephric kidneys form in the pelvis, they ascend to their ultimate destination in the abdomen. As they do so, they receive renal blood vessels. Although the inferior blood vessels usually degenerate as superior ones appear, sometimes the inferior vessels do not degenerate. Consequently, some individuals (about 30%) develop multiple renal vessels.

### CHECKPOINT

26. Which type of embryonic tissue develops into nephrons?

27. Which tissue gives rise to collecting ducts, calyces, renal pelvis, and ureters?

### AGING AND THE URINARY SYSTEM

#### OBJECTIVE

- Describe the effects of aging on the urinary system.

With aging, the kidneys shrink in size, have a decreased blood flow, and filter less blood. These age-related changes in kidney size and function seem to be linked to a progressive reduction in blood supply to the kidneys as an individual gets older; for example, blood vessels such as the glomeruli become damaged or decrease in number. The mass of the two kidneys decreases from an average of nearly 300 g in 20-year-olds to less than 200 g by age 80, a decrease of about one-third. Likewise, renal blood flow and filtration rate decline by 50% between ages 40 and 70. By age 80, about 40% of glomeruli are not functioning and thus filtration, reabsorption, and secretion decrease. Kidney diseases that become more common with age include acute and chronic kidney inflammations and renal calculi (kidney stones). Because the sensation of thirst diminishes with age, older individuals also are susceptible to dehydration. Urinary bladder changes that occur with aging include a reduction
Degenerating pronephros
Metanephros: Ureteric bud
Metanephric mesoderm
Mesonephros
Urogenital ridges
Mesonephric duct
Gonad

(a) Fifth week
(b) Sixth week
(c) Seventh week
(d) Eighth week

When do the kidneys begin to develop?

in size and capacity and weakening of the muscles. Urinary tract infections are more common among the elderly, as are polyuria (excessive urine production), nocturia (excessive urination at night), increased frequency of urination, dysuria (painful urination), urinary retention or incontinence, and hematuria (blood in the urine).

CHECKPOINT

28. To what extent do kidney mass and filtration rate decrease with age?

To appreciate the many ways that the urinary system contributes to homeostasis of other body systems, examine Focus on Homeostasis: The Urinary System. Next, in Chapter 27, we will see how the kidneys and lungs contribute to maintenance of homeostasis of body fluid volume, electrolyte levels in body fluids, and acid–base balance.
Focus on Homeostasis

**BODY SYSTEM** | **CONTRIBUTION OF THE URINARY SYSTEM**
--- | ---
For all body systems | Kidneys regulate the volume, composition, and pH of body fluids by removing wastes and excess substances from blood and excreting them in urine; the ureters transport urine from the kidneys to the urinary bladder, which stores urine until it is eliminated through the urethra.

Integumentary system | Kidneys and skin both contribute to synthesis of calcitriol, the active form of vitamin D.

Skeletal system | Kidneys help adjust levels of blood calcium and phosphates, needed for building extracellular bone matrix.

Muscular system | Kidneys help adjust level of blood calcium, needed for contraction of muscle.

Nervous system | Kidneys perform gluconeogenesis, which provides glucose for ATP production in neurons, especially during fasting or starvation.

Endocrine system | Kidneys participate in synthesis of calcitriol, the active form of vitamin D, and release erythropoietin, the hormone that stimulates production of red blood cells.

Cardiovascular system | By increasing or decreasing their reabsorption of water filtered from blood, the kidneys help adjust blood volume and blood pressure; renin released by juxtaglomerular cells in the kidneys raises blood pressure; some bilirubin from hemoglobin breakdown is converted to a yellow pigment (urobilin), which is excreted in urine.

Lymphatic system and immunity | By increasing or decreasing their reabsorption of water filtered from blood, the kidneys help adjust the volume of interstitial fluid and lymph; urine flushes microbes out of the urethra.

Respiratory system | Kidneys and lungs cooperate in adjusting pH of body fluids.

Digestive system | Kidneys help synthesize calcitriol, the active form of vitamin D, which is needed for absorption of dietary calcium.

Reproductive systems | In males, the portion of the urethra that extends through the prostate and penis is a passageway for semen as well as urine.
### DISORDERS: HOMEOSTATIC IMBALANCES

#### Renal Calculi

The crystals of salts present in urine occasionally precipitate and solidify into insoluble stones called renal calculi (calcui = pebbles) or kidney stones. They commonly contain crystals of calcium oxalate, uric acid, or calcium phosphate. Conditions leading to calculus formation include the ingestion of excessive calcium, low water intake, abnormally alkaline or acidic urine, and overactivity of the parathyroid glands. When a stone lodges in a narrow passage, such as a ureter, the pain can be intense. **Shock-wave lithotripsy** (LITH-ô-lith-ô-trîp’sé; litho = stone) is a procedure that uses high-energy shock waves to disintegrate kidney stones and offers an alternative to surgical removal. Once the kidney stone is located using x-rays, a device called a lithotripter delivers brief, high-intensity sound waves through a water or gel-filled cushion placed under the back. Over a period of 30 to 60 minutes, 1000 or more shock waves pulverize the stone, creating fragments that are small enough to wash out in the urine.

#### Urinary Tract Infections

The term **urinary tract infection (UTI)** is used to describe either an infection of a part of the urinary system or the presence of large numbers of microbes in urine. UTIs are more common in females due to the shorter length of the urethra. Symptoms include painful or burning urination, urgent and frequent urination, low back pain, and bedwetting. UTIs include urethritis (inflammation of the urethra), cystitis (inflammation of the urinary bladder), and pyelonephritis (inflammation of the kidneys). If pyelonephritis becomes chronic, scar tissue can form in the kidneys and severely impair their function. Drinking cranberry juice can prevent the attachment of _E. coli_ bacteria to the lining of the urinary bladder so that they are more readily flushed away during urination.

#### Glomerular Diseases

A variety of conditions may damage the kidney glomeruli, either directly or indirectly because of disease elsewhere in the body. Typically, the filtration membrane sustains damage, and its permeability increases.

**Glomerulonephritis** is an inflammation of the kidney that involves the glomeruli. One of the most common causes is an allergic reaction to the toxins produced by streptococcal bacteria that have recently infected another part of the body, especially the throat. The glomeruli become so inflamed, swollen, and engorged with blood that the filtration membranes allow blood cells and plasma proteins to enter the filtrate. As a result, the urine contains many erythrocytes (hematuria) and a lot of protein. The glomeruli may be permanently damaged, leading to chronic renal failure.

**Nephrotic syndrome** is a condition characterized by **proteinuria** (protein in the urine) and **hyperlipidemia** (high blood levels of cholesterol, phospholipids, and triglycerides). The proteinuria is due to an increased permeability of the filtration membrane, which permits proteins, especially albumin, to escape from blood into urine. Loss of albumin results in hypoaalbuminemia (low blood albumin level) once liver production of albumin fails to meet increased urinary losses. Edema, usually seen around the eyes, ankles, feet, and abdomen, occurs in nephrotic syndrome because loss of albumin from the blood decreases blood colloid osmotic pressure. Nephrotic syndrome is associated with several glomerular diseases of unknown cause, as well as with systemic disorders such as diabetes mellitus, systemic lupus erythematosus (SLE), a variety of cancers, and AIDS.

#### Renal Failure

Renal failure is a decrease or cessation of glomerular filtration. In **acute renal failure (ARF)**, the kidneys abruptly stop working entirely (or almost entirely). The main feature of ARF is the suppression of urine flow, usually characterized either by **oliguria** (daily urine output between 50 mL and 250 mL), or by **anuria** (daily urine output less than 50 mL). Causes include low blood volume (for example, due to hemorrhage), decreased cardiac output, damaged renal tubes, kidney stones, the dyes used to visualize blood vessels in angiograms, nonsteroidal anti-inflammatory drugs, and some antibiotic drugs. It is also common in people who suffer a devastating illness or overwhelming traumatic injury; in such cases it may be related to a more general organ failure known as multiple organ dysfunction syndrome (MODS).

Renal failure causes a multitude of problems. There is edema due to salt and water retention and metabolic acidosis due to an inability of the kidneys to excrete acidic substances. In the blood, urea builds up due to impaired renal excretion of metabolic waste products and potassium level rises, which can lead to cardiac arrest. Often, there is anemia because the kidneys no longer produce enough erythropoietin for adequate red blood cell production. Because the kidneys are no longer able to convert vitamin D to calcitriol, which is needed for adequate calcium absorption from the small intestine, osteomalacia also may occur.

**Chronic renal failure (CRF)** refers to a progressive and usually irreversible decline in glomerular filtration rate (GFR). CRF may result from chronic glomerulonephritis, pyelonephritis, polycystic kidney disease, or traumatic loss of kidney tissue. CRF develops in three stages. In the first stage, **diminished renal reserve**, nephrons are destroyed until about 75% of the functioning nephrons are lost. At this stage, a person may have no signs or symptoms because the remaining nephrons enlarge and take over the function of those that have been lost. Once 75% of the nephrons are lost, the person enters the second stage, called **renal insufficiency**, characterized by a decrease in GFR and increased blood levels of nitrogen-containing wastes and creatinine. Also, the kidneys cannot effectively concentrate or dilute the urine. The final stage, called **end-stage renal failure**, occurs when about 90% of the nephrons have been lost. At this stage, GFR diminishes to 10–15% of normal, oliguria is present, and blood levels of nitrogen-containing wastes and creatinine increase further. People with end-stage renal failure need dialysis therapy and are possible candidates for a kidney transplant operation.

#### Polycystic Kidney Disease

**Polycystic kidney disease (PKD)** is one of the most common inherited disorders. In PKD, the kidney tubules become riddled with hundreds or thousands of cysts (fluid-filled cavities). In addition, inappropriate apoptosis (programmed cell death) of cells in noncystic tubules leads to progressive impairment of renal function and eventually to end-stage renal failure.

People with PKD also may have cysts and apoptosis in the liver, pancreas, spleen, and gonads; increased risk of cerebral aneurysms; heart valve defects; and diverticuli in the colon. Typically, symptoms are not noticed until adulthood, when patients may have back pain, urinary tract infections, blood in the urine, hypertension, and large abdominal masses. Using drugs to restore normal blood pressure, restricting protein and salt in the diet, and controlling urinary tract infections may slow progression to renal failure.
Urinary Bladder Cancer

Each year, nearly 12,000 Americans die from urinary bladder cancer. It generally strikes people over 50 years of age and is three times more likely to develop in males than females. The disease is typically painless as it develops, but in most cases blood in the urine is a primary sign of the disease. Less often, people experience painful and/or frequent urination.

As long as the disease is identified early and treated promptly, the prognosis is favorable. Fortunately, about 75% of the urinary bladder cancers are confined to the epithelium of the urinary bladder and are easily removed by surgery. The lesions tend to be low-grade, meaning that they have only a small potential for metastasis.

Urinary bladder cancer is frequently the result of a carcinogen. About half of all cases occur in people who smoke or have at some time smoked cigarettes. The cancer also tends to develop in people who are exposed to chemicals called aromatic amines. Workers in the leather, dye, rubber, and aluminum industries, as well as painters, are often exposed to these chemicals.

### MEDICAL TERMINOLOGY

- **Azotemia** (az-ō-TÉ-mē-ə; azot- = nitrogen; -emia = condition of blood) Presence of urea or other nitrogen-containing substances in the blood.
- **Cystocele** (SIS-to-se-lē; cysto- = bladder; -cele = hernia or rupture) Hernia of the urinary bladder.
- **Diabetic kidney disease** A disorder caused by diabetes mellitus in which glomeruli are damaged. The result is the leakage of proteins into the urine and a reduction in the ability of the kidney to remove water and waste.
- **Dysuria** (dis-U-rē-a; dys- = painful; uri- = urine) Painful urination.
- **Enuresis** (en’-ū-Řē-sis = to void urine) Involuntary voiding of urine after the age at which voluntary control has typically been attained.
- **Hydronephrosis** (hi’-drō-ne-frÔ-sis; hydro- = water; nephros = kidney; -osis = condition) Swelling of the kidney due to dilatation of the renal pelvis and calyces as a result of an obstruction to the flow of urine. It may be due to a congenital abnormality, a narrowing of the ureter, a kidney stone, or an enlarged prostate.
- **Intravenous pyelogram** (in’-tra-VĒ-nus Pl-e’-ō-gram’; intra- = within; veno- = vein; pyelo- = pelvis of kidney; -gram = record) (or IVP) Radiograph (x-ray) of the kidneys, ureters, and urinary bladder after venous injection of a radiopaque contrast medium.
- **Nephropathy** (ne-FROP-a-thē; neph- = kidney; -pathos = suffering) Any disease of the kidneys. Types include analgesic (from long-term and excessive use of drugs such as ibuprofen), lead (from ingestion of lead-based paint), and solvent (from carbon tetrachloride and other solvents).

### Anatomy and Histology of the Kidneys (p. 1020)

1. The kidneys are retroperitoneal organs attached to the posterior abdominal wall.
2. Three layers of tissue surround the kidneys: renal capsule, adipose capsule, and renal fascia.
3. Internally, the kidneys consist of a renal cortex, a renal medulla, renal pyramids, renal papillae, renal columns, major and minor calyces, and a renal pelvis.
4. Blood flows into the kidney through the renal artery and successively into segmental, interlobar, arcuate, and interlobular arteries; afferent arterioles; glomerular capillaries; efferent arterioles; peritubular capillaries and vasa recta; and interlobular, arcuate, and interlobular veins before flowing out of the kidney through the renal vein.

---

**STUDY OUTLINE**

**Introduction (p. 1018)**

1. The organs of the urinary system are the kidneys, ureters, urinary bladder, and urethra.
2. After the kidneys filter blood and return most water and many solutes to the bloodstream, the remaining water and solutes constitute urine.

**Overview of Kidney Functions (p. 1020)**

1. The kidneys regulate blood ionic composition, blood osmolality, blood volume, blood pressure, and blood pH.
2. The kidneys also perform gluconeogenesis, release calcitriol and erythropoietin, and excrete wastes and foreign substances.

---

**Nocturnal enuresis** (nok-TUR-nal en’-ō-Řē-sis) Discharge of urine during sleep, resulting in bed-wetting; occurs in about 15% of 5-year-old children and generally resolves spontaneously, afflicting only about 1% of adults. It may have a genetic basis, as bed-wetting occurs more often in identical twins than in fraternal twins and more often in children whose parents or siblings were bed-wetters. Possible causes include smaller-than-normal bladder capacity, failure to awaken in response to a full bladder, and abnormal production of urine at night. Also referred to as nocturia.

**Polyuria** (pol’-ē-ū-řē-a; poly- = too much) Excessive urine formation. It may occur in conditions such as diabetes mellitus and glomerulonephritis.

**Stricture** (STRIK-chur) Narrowing of the lumen of a canal or hollow organ, as may occur in the ureter, urethra, or any other tubular structure in the body.

**Uremia** (ū-Řē-mē-ə; emia = condition of blood) Toxic levels of urea in the blood resulting from severe malfunction of the kidneys.

**Urinary retention** A failure to completely or normally void urine; may be due to an obstruction in the urethra or neck of the urinary bladder, to nervous contraction of the urethra, or to lack of urge to urinate. In men, an enlarged prostate may constrict the urethra and cause urinary retention. If urinary retention is prolonged, a catheter (slender rubber drainage tube) must be placed into the urethra to drain the urine.
Tubular Reabsorption and Tubular Secretion (p. 1034)

1. Tubular reabsorption is a selective process that reclaims materials from tubular fluid and returns them to the bloodstream. Reabsorbed substances include water, glucose, amino acids, urea, and ions, such as sodium, chloride, potassium, bicarbonate, and phosphate (Table 26.3 on page 1035).

2. Some substances not needed by the body are removed from the blood and discharged into the urine via tubular secretion. Included are ions (K⁺, H⁺, and NH₄⁺), urea, creatinine, and certain drugs.

3. Reabsorption routes include both paracellular (between tubule cells) and transcellular (across tubule cells) routes.

4. The maximum amount of a substance that can be reabsorbed per unit time is called the transport maximum (Tm).

5. About 90% of water reabsorption is obligatory; it occurs via osmosis, together with reabsorption of solutes, and is not hormonally regulated. The remaining 10% is facultative water reabsorption, which varies according to body needs and is regulated by ADH.

6. Na⁺ ions are reabsorbed throughout the basolateral membrane via primary active transport.

7. In the proximal convoluted tubule, sodium ions are reabsorbed through the apical membranes via Na⁺–glucose symporters and Na⁺/H⁺ antporters; water is reabsorbed via osmosis; Cl⁻, K⁺, Ca²⁺, Mg²⁺, and urea are reabsorbed via passive diffusion; and NH₃ and NH₄⁺ are secreted.

8. The loop of Henle reabsors 20–30% of the filtered Na⁺, K⁺, Ca²⁺, and HCO₃⁻; 35% of the filtered Cl⁻; and 15% of the filtered water.

9. The distal convoluted tubule reabsorbs sodium and chloride ions via Na⁺–Cl⁻ symporters.

10. In the collecting duct, principal cells reabsorb Na⁺ and secrete K⁺; intercalated cells reabsorb K⁺ and HCO₃⁻ and secrete H⁺.

11. Angiotensin II, aldosterone, antidiuretic hormone, atrial natriuretic peptide, and parathyroid hormone regulate solute and water reabsorption, as summarized in Table 26.4 on page 1042.

Production of Dilute and Concentrated Urine (p. 1042)

1. In the absence of ADH, the kidneys produce dilute urine; renal tubules absorb more solutes than water.

2. In the presence of ADH, the kidneys produce concentrated urine; large amounts of water are reabsorbed from the tubular fluid into interstitial fluid, increasing solute concentration of the urine.

3. The countercurrent multiplier establishes an osmotic gradient in the interstitial fluid of the renal medulla that enables production of concentrated urine when ADH is present.

Evaluation of Kidney Function (p. 1047)

1. A urinalysis is an analysis of the volume and physical, chemical, and microscopic properties of a urine sample. Table 26.5 on page 1047 summarizes the principal physical characteristics of normal urine.

2. Chemically, normal urine contains about 95% water and 5% solutes. The solutes normally include urea, creatinine, uric acid, urobilinogen, and various ions.

3. Table 26.6 on page 1048 lists several abnormal components that can be detected in a urinalysis, including albumin, glucose, red and white blood cells, ketone bodies, bilirubin, excessive urobilinogen, casts, and microbes.

4. Renal clearance refers to the ability of the kidneys to clear (remove) a specific substance from blood.

Urine Transportation, Storage, and Elimination (p. 1049)

1. The ureters are retroperitoneal and consist of a mucosa, muscularis, and adventitia. They transport urine from the renal pelvis to the urinary bladder, primarily via peristalsis.

2. The urinary bladder is located in the pelvic cavity posterior to the pubic symphysis; its function is to store urine before micturition.

3. The urinary bladder consists of a mucosa with rugae, a muscularis (detrusor muscle), and an adventitia (serosa over the superior surface).
4. The micturition reflex discharges urine from the urinary bladder via parasympathetic impulses that cause contraction of the detrusor muscle and relaxation of the internal urethral sphincter muscle and via inhibition of impulses in somatic motor neurons to the external urethral sphincter.

5. The urethra is a tube leading from the floor of the urinary bladder to the exterior. Its anatomy and histology differ in females and males. In both sexes, the urethra functions to discharge urine from the body; in males, it discharges semen as well.

Waste Management in Other Body Systems (p. 1052)

1. Besides the kidneys, several other tissues, organs, and processes temporarily confine wastes, transport waste materials for disposal, recycle materials, and excrete excess or toxic substances.

2. Buffers bind excess H⁺, the blood transports wastes, the liver converts toxic substances into less toxic ones, the lungs exhale CO₂, sweat glands help eliminate excess heat, and the gastrointestinal tract eliminates solid wastes.

Development of the Urinary System (p. 1053)

1. The kidneys develop from intermediate mesoderm.

2. The kidneys develop in the following sequence: pronephros, mesonephros, and metanephros. Only the metanephros remains and develops into a functional kidney.

Aging and the Urinary System (p. 1053)

1. With aging, the kidneys shrink in size, have a decreased blood flow, and filter less blood.

2. Common problems related to aging include urinary tract infections, increased frequency of urination, urinary retention or incontinence, and renal calculi.

SELF-QUIZ QUESTIONS

Fill in the blanks in the following statements.

1. The renal corpuscle consists of the _____ and _____.

2. Discharge of urine from the urinary bladder is called _____.

Indicate whether the following statements are true or false.

3. The most superficial region of the internal kidney is the renal medulla.

4. When dilute urine is being formed, the osmolarity of the fluid in the tubular lumen increases as it flows down the descending limb of the loop of Henle, decreases as it flows up the ascending limb, and continues to decrease as it flows through the rest of the nephron and collecting duct.

Choose the one best answer to the following questions.

5. Which of the following statements are correct? (1) Glomerular filtration rate (GFR) is directly related to the pressures that determine net filtration pressure. (2) Angiotensin II and atrial natriuretic peptide help regulate GFR. (3) Mechanisms that regulate GFR include adjustment of blood flow into and out of the glomerulus and by altering the glomerular capillary surface area available for filtration. (4) GFR increases when blood flow into glomerular capillaries decreases. (5) Normally, GFR increases very little when systemic blood pressure rises.

6. Which of the following hormones affect Na⁺, Cl⁻, Ca²⁺, and water reabsorption and K⁺ secretion by the renal tubules? (1) angiotensin II, (2) aldosterone, (3) ADH, (4) atrial natriuretic peptide, (5) thyroid hormone, (6) parathyroid hormone.

7. Which of the following are features of the renal corpuscle that enhance its filtering capacity? (1) large glomerular capillary surface area, (2) thick, selectively permeable filtration membrane, (3) high capillary hydrostatic pressure, (4) high glomerular capillary pressure, (5) mesangial cells regulating the filtering surface area.

8. Given the following values, calculate the net filtration pressure: (1) glomerular blood hydrostatic pressure = 40 mmHg, (2) capsular hydrostatic pressure = 10 mmHg, (3) blood colloid osmotic pressure = 30 mmHg.

9. The micturition reflex (1) is initiated by stretch receptors in the bladder, (2) relies on parasympathetic impulses from the micturition center in S2 and S3, (3) results in contraction of the detrusor muscle, (4) results in contraction of the internal urethral sphincter muscle, (5) inhibits motor neurons in the external urethral sphincter.

10. Which of the following are mechanisms that control GFR? (1) renal autoregulation, (2) neural regulation, (3) hormonal regulation, (4) chemical regulation of ions, (5) presence or absence of a transporter.

11. Place the route of blood flow through the kidney in the correct order:

(a) segmental arteries (b) vasa recta
(c) arcuate arteries (d) peritubular venules
(e) interlobular veins (f) renal vein
(g) renal artery (h) interlobar arteries
(i) peritubular capillaries (j) efferent arterioles
(k) interlobar veins (l) glomeruli
(m) arcuate veins (n) afferent arterioles
(o) interlobar arteries
12. Place the route of filtrate flow in the correct order from its origin to the ureter:
   (a) minor calyx
   (b) ascending limb of loop of Henle
   (c) papillary duct
   (d) distal convoluted tubule
   (e) major calyx
   (f) descending limb of loop of Henle
   (g) proximal convoluted tubule
   (h) collecting duct
   (i) renal pelvis

13. Match the following:
   (a) cells in the last portion of the distal convoluted tubule and in the collecting ducts; regulated by ADH and aldosterone
   (b) a capillary network lying in the glomerular capsule and functioning in filtration
   (c) the functional unit of the kidney
   (d) drains into a collecting duct
   (e) combined glomerulus and glomerular capsule; where plasma is filtered
   (f) the visceral layer of the glomerular capsule consisting of modified simple squamous epithelial cells
   (g) cells of the final portion of the ascending limb of the loop of Henle that make contact with the afferent arteriole
   (h) site of obligatory water reabsorption
   (i) pores in the glomerular endothelial cells that allow filtration of blood solutes but not blood cells and platelets
   (j) can secrete H⁺ against a concentration gradient
   (k) modified smooth muscle cells in the wall of the afferent arteriole

14. Match the following:
   (a) measure of blood nitrogen resulting from the catabolism and deamination of amino acids
   (b) produced from the catabolism of creatine phosphate in skeletal muscle
   (c) volume of blood that is cleared of a substance per unit of time
   (d) can result from diabetes mellitus
   (e) insoluble stones of crystallized salts
   (f) usually indicates a pathological condition
   (g) lack of voluntary control of micturition
   (h) can be caused by damage to the filtration membranes

15. Match the following:
   (a) membrane proteins that function as water channels
   (b) a secondary active transport process that achieves Na⁺ reabsorption, returns filtered HCO₃⁻ and water to the peritubular capillaries, and secretes H⁺
   (c) stimulates principal cells to secrete more K⁺ into tubular fluid and absorb more Na⁺ and Cl⁻ into tubular fluid
   (d) enzyme secreted by juxtaglomerular cells
   (e) reduces glomerular filtration rate; increases blood volume and pressure
   (f) inhibits Na⁺ and H₂O reabsorption in the proximal convoluted tubules and collecting ducts
   (g) regulates facultative water reabsorption by increasing the water permeability of principal cells in the distal convoluted tubules and collecting ducts
   (h) reabsorb Na⁺ together with a variety of other solutes
   (i) stimulates cells in the distal convoluted tubule to reabsorb more calcium into the blood

1060 CHAPTER 26 • THE URINARY SYSTEM
CRITICAL THINKING QUESTIONS

1. Imagine the discovery of a new toxin that blocks renal tubule reabsorption but does not affect filtration. Predict the short-term effects of this toxin.

2. For each of the following urinalysis results, indicate whether you should be concerned or not and why: (a) dark yellow urine that is turbid; (b) ammonia-like odor of the urine; (c) presence of excessive albumin; (d) presence of epithelial cell casts; (e) pH of 5.5; (f) hematuria.

ANSWERS TO FIGURE QUESTIONS

26.1 The kidneys, ureters, urinary bladder, and urethra are the components of the urinary system.

26.2 The kidneys are retroperitoneal because they are posterior to the peritoneum.

26.3 Blood vessels, lymphatic vessels, nerves, and a ureter pass through the renal hilum.

26.4 About 1200 mL of blood enters the renal arteries each minute.

26.5 Cortical nephrons have glomeruli in the superficial renal cortex, and their short loops of Henle penetrate only into the superficial renal medulla. Juxtamedullary nephrons have glomeruli deep in the renal cortex, and their long loops of Henle extend through the renal medulla nearly to the renal papilla.

26.6 This section must pass through the renal cortex because there are no renal corpuscles in the renal medulla.

26.7 Secreted penicillin is being removed from the bloodstream.

26.8 Endothelial fenestrations (pores) in glomerular capillaries are too small for red blood cells to pass through.

26.9 Obstruction of the right ureter would increase CHP and thus decrease NFP in the right kidney; the obstruction would have no effect on the left kidney.

26.10 Auto means self; tubuloglomerular feedback is an example of autoregulation because it takes place entirely within the kidneys.

26.11 The tight junctions between tubule cells form a barrier that prevents diffusion of transporter, channel, and pump proteins between the apical and basolateral membranes.

26.12 Glucose enters a PCT cell via a Na⁺–glucose symporter in the apical membrane and leaves via facilitated diffusion through the basolateral membrane.

26.13 The electrochemical gradient promotes movement of Na⁺ into the tubule cell through the apical membrane antiporters.

26.14 Reabsorption of the solutes creates an osmotic gradient that promotes the reabsorption of water via osmosis.

26.15 This is considered secondary active transport because the symporter uses the energy stored in the concentration gradient of Na⁺ between extracellular fluid and the cytosol. No water is reabsorbed here because the thick ascending limb of the loop of Henle is virtually impermeable to water.

26.16 In principal cells, aldosterone stimulates secretion of K⁺ and reabsorption of Na⁺ by increasing the activity of sodium-potassium pumps and number of leakage channels for Na⁺ and K⁺.

26.17 Aldosterone and atrial natriuretic peptide influence renal water reabsorption along with ADH.

26.18 Dilute urine is produced when the thick ascending limb of the loop of Henle, the distal convoluted tubule, and the collecting duct reabsorb more solutes than water.

26.19 The high osmolarity of interstitial fluid in the renal medulla is due mainly to Na⁺, Cl⁻, and urea.

26.20 Secretion occurs in the proximal convoluted tubule, the loop of Henle, and the collecting duct.

26.21 Lack of voluntary control over micturition is termed urinary incontinence.

26.22 The three subdivisions of the male urethra are the prostatic urethra, membranous urethra, and spongy urethra.

26.23 The kidneys start to form during the third week of development.
The regulation of the volume and composition of body fluids, their distribution throughout the body, and balancing the pH of body fluids is crucial to maintaining overall homeostasis and health.

In Chapter 26 you learned how the kidneys form urine. One important function of the kidneys is to help maintain fluid balance in the body. The water and dissolved solutes throughout the body constitute the **body fluids**. Regulatory mechanisms involving the kidneys and other organs normally maintain homeostasis of the body fluids. Malfunction in any or all of them may seriously endanger the functioning of organs throughout the body. In this chapter, we will explore the mechanisms that regulate the volume and distribution of body fluids and examine the factors that determine the concentrations of solutes and the pH of body fluids.
FLUID COMPARTMENTS AND FLUID BALANCE

**OBJECTIVES**

- Compare the locations of intracellular fluid (ICF) and extracellular fluid (ECF), and describe the various fluid compartments of the body.
- Describe the sources of water and solute gain and loss, and explain how each is regulated.
- Explain how fluids move between compartments.

In lean adults, body fluids constitute between 55% and 60% of total body mass in females and males, respectively (Figure 27.1). Body fluids are present in two main “compartments”—inside cells and outside cells. About two-thirds of body fluid is intracellular fluid (ICF) (intra- = within) or cytosol, the fluid within cells. The other third, called extracellular fluid (ECF) (extra- = outside) is outside cells and includes all other body fluids. About 80% of the ECF is interstitial fluid (inter- = between), which occupies the microscopic spaces between tissue cells, and 20% of the ECF is plasma, the liquid portion of the blood. Other extracellular fluids that are grouped with interstitial fluid include lymph in lymphatic vessels; cerebrospinal fluid in the nervous system; synovial fluid in joints; aqueous humor and vitreous body in the eyes; endolymph and perilymph in the ears; and pleural, pericardial, and peritoneal fluids between serous membranes.

Two general “barriers” separate intracellular fluid, interstitial fluid, and blood plasma.

1. The plasma membrane of individual cells separates intracellular fluid from the surrounding interstitial fluid. You learned in Chapter 3 that the plasma membrane is a selectively permeable barrier: It allows some substances to cross but blocks the movement of other substances. In addition, active transport pumps work continuously to maintain different concentrations of certain ions in the cytosol and interstitial fluid.

2. Blood vessel walls divide the interstitial fluid from blood plasma. Only in capillaries, the smallest blood vessels, are the walls thin enough and leaky enough to permit the exchange of water and solutes between blood plasma and interstitial fluid.

The body is in fluid balance when the required amounts of water and solutes are present and are correctly proportioned among the various compartments. Water is by far the largest single component of the body, making up 45–75% of total body mass, depending on age and gender.

**Figure 27.1** Body fluid compartments.

The term body fluid refers to body water and its dissolved substances.

(a) Distribution of body solids and fluids in an average lean, adult female and male

(b) Exchange of water among body fluid compartments

What is the approximate volume of blood plasma in a lean 60-kg male? In a lean 60-kg female? (Note: One liter of body fluid has a mass of 1 kilogram.)
The processes of filtration, reabsorption, diffusion, and osmosis allow continual exchange of water and solutes among body fluid compartments (Figure 27.1b). Yet the volume of fluid in each compartment remains remarkably stable. The pressures that promote filtration of fluid from blood capillaries and reabsorption of fluid back into capillaries can be reviewed in Figure 21.7 on page 771. Because osmosis is the primary means of water movement between intracellular fluid and interstitial fluid, the concentration of solutes in these fluids determines the direction of water movement. Because most solutes in body fluids are electrolytes, inorganic compounds that dissociate into ions, fluid balance is closely related to electrolyte balance. Because intake of water and electrolytes rarely occurs in exactly the same proportions as their presence in body fluids, the ability of the kidneys to excrete excess water by producing dilute urine, or to excrete excess electrolytes by producing concentrated urine, is of utmost importance in the maintenance of homeostasis.

**Sources of Body Water Gain and Loss**

The body can gain water by ingestion and by metabolic synthesis (Figure 27.2). The main sources of body water are ingested liquids (about 1600 mL) and moist foods (about 700 mL) absorbed from the gastrointestinal (GI) tract, which total about 2300 mL/day. The other source of water is metabolic water that is produced in the body mainly when electrons are accepted by oxygen during aerobic cellular respiration (see Figure 25.2 on page 981) and to a smaller extent during dehydration synthesis reactions (see Figure 2.15 on page 45). Metabolic water gain accounts for only 200 mL/day. Daily water gain from these two sources totals about 2500 mL.

Normally, body fluid volume remains constant because water loss equals water gain. Water loss occurs in four ways (Figure 27.2). Each day the kidneys excrete about 1500 mL in urine, the skin evaporates about 600 mL (400 mL through insensible perspiration, sweat that evaporates before it is perceived as moisture, and 200 mL as sweat), the lungs exhale about 300 mL as water vapor, and the gastrointestinal tract eliminates about 100 mL in feces. In women of reproductive age, additional water is lost in menstrual flow. On average, daily water loss totals about 2500 mL. The amount of water lost by a given route can vary considerably over time. For example, water may literally pour from the skin in the form of sweat during strenuous exertion. In other cases, water may be lost in diarrhea during a GI tract infection.

**Regulation of Body Water Gain**

The volume of metabolic water formed in the body depends entirely on the level of aerobic cellular respiration, which reflects the demand for ATP in body cells. When more ATP is produced, more water is formed. Body water gain is regulated mainly by the volume of water intake, or how much fluid you drink. An area in the hypothalamus known as the thirst center governs the urge to drink.

When water loss is greater than water gain, dehydration—a decrease in volume and an increase in osmolarity of body fluids—stimulates thirst (Figure 27.3). When body mass decreases by 2% due to fluid loss, mild dehydration exists. A decrease in blood volume causes blood pressure to fall. This change stimulates the kidneys to release renin, which promotes the formation of angiotensin II. Increased nerve impulses from osmoreceptors in the hypothalamus, triggered by increased blood osmolarity, and increased angiotensin II in the blood both stimulate the thirst center in the hypothalamus. Other signals that stimulate thirst come from (1) neurons in the mouth that detect dryness due to a decreased flow of saliva and (2) baroreceptors that detect lowered blood pressure in the heart and blood vessels. As a result, the sensation of thirst increases, which usually leads to increased fluid intake (if fluids are available) and restoration of normal fluid volume. Overall, fluid gain balances fluid loss. Sometimes, however, the sensation of thirst does not occur quickly enough or access to fluids is restricted, and significant dehydration ensues. This happens most often in elderly people, in infants, and in those who are in a confused mental state. When heavy sweating or fluid loss from diarrhea or vomiting occurs, it is wise to start replacing body fluids by drinking fluids even before the sensation of thirst occurs.
The extent of urinary salt (water or solutes) occurs mainly by control of their loss in urine. Even though the loss of water and solutes through sweating and exhalation increases during exercise, elimination of excess water gain.

Does regulation of these pathways occur via negative or positive feedback? Why?

Figure 27.3 Pathways through which dehydration stimulates thirst.

Regulation of Water and Solute Loss

Even though the loss of water and solutes through sweating and exhalation increases during exercise, elimination of excess body water or solutes occurs mainly by control of their loss in urine. The extent of urinary salt (NaCl) loss is the main factor that determines body fluid volume. The reason for this is that “water follows solutes” in osmosis, and the two main solutes in extracellular fluid (and in urine) are sodium ions (Na⁺) and chloride ions (Cl⁻). In a similar way, the main factor that determines body fluid osmolarity is the extent of urinary water loss.

Because our daily diet contains a highly variable amount of NaCl, urinary excretion of Na⁺ and Cl⁻ must also vary to maintain homeostasis. Hormonal changes regulate the urinary loss of these ions, which in turn affects blood volume. Figure 27.4 depicts the sequence of changes that occur after a salty meal. The increased intake of NaCl produces an increase in plasma levels of Na⁺ and Cl⁻ (the major contributors to osmolarity of extracellular fluid). As a result, the osmolarity of interstitial fluid increases, which causes movement of water from intracellular fluid into interstitial fluid and then into plasma. Such water movement increases blood volume.

The three most important hormones that regulate the extent of renal Na⁺ and Cl⁻ reabsorption (and thus how much is lost in the urine) are angiotensin II, aldosterone, and atrial natriuretic peptide (ANP). When your body is dehydrated, angiotensin II and aldosterone promote urinary reabsorption of Na⁺ and Cl⁻ (and water by osmosis with the electrolytes), conserving the volume of body fluids by reducing urinary loss. An increase in blood volume, as might occur after you finish one or more supersized drinks, stretches the atria of the heart and promotes release of atrial natriuretic peptide. ANP promotes natriuresis, elevated urinary excretion of Na⁺ (and Cl⁻) followed by water excretion, which decreases blood volume. An increase in blood volume also slows release of renin from juxtaglomerular cells of the kidneys. When renin level declines, less angiotensin II is formed. Decline in angiotensin II from a moderate level to a low level increases glomerular filtration rate and reduces Na⁺, Cl⁻, and water reabsorption in the kidney tubules. In addition, less angiotensin II leads to lower levels of aldosterone, which causes reabsorption of filtered Na⁺ and Cl⁻ to slow in the renal collecting ducts. More filtered Na⁺ and Cl⁻ thus remain in the tubular fluid to be excreted in the urine. The osmotic consequence of excreting more Na⁺ and Cl⁻ is loss of more water in urine, which decreases blood volume and blood pressure.

The major hormone that regulates water loss is antidiuretic hormone (ADH). This hormone, also known as vasopressin, is produced by neurosecretory cells that extend from the hypothalamus to the posterior pituitary. In addition to stimulating the thirst mechanism, an increase in the osmolarity of body fluids stimulates release of ADH (see Figure 26.17 on page 1041). ADH promotes the insertion of water-channel proteins (aquaporin-2) into the apical membranes of principal cells in the collecting ducts of the kidneys. As a result, the permeability of these cells to water increases. Water molecules move by osmosis from the renal tubular fluid into the cells and then from the cells into the bloodstream. The result is production of a small volume of very concentrated urine (see page 1043). Intake of water in response to the thirst mechanism decreases the osmolarity of blood and interstitial fluid. Within minutes, ADH secretion shuts down, and soon its blood level is close to zero. When the principal cells are not stimulated by ADH, aquaporin-2 molecules are removed.
The three main hormones that regulate renal Na\(^+\) and Cl\(^-\) reabsorption (and thus the amount lost in the urine) are angiotensin II, aldosterone, and atrial natriuretic peptide.

How does hyperaldosteronism (excessive aldosterone secretion) cause edema?
Movement of Water Between Body Fluid Compartments

Normally, cells neither shrink nor swell because intracellular and interstitial fluids have the same osmolarity. Changes in the osmolarity of interstitial fluid, however, cause fluid imbalances. An increase in the osmolarity of interstitial fluid draws water out of cells, and they shrink slightly. A decrease in the osmolarity of interstitial fluid, by contrast, causes cells to swell. Changes in osmolarity most often result from changes in the concentration of Na⁺.

A decrease in the osmolarity of interstitial fluid, as may occur after drinking a large volume of water, inhibits secretion of ADH. Normally, the kidneys then excrete a large volume of dilute urine, which restores the osmotic pressure of body fluids to normal. As a result, body cells swell only slightly, and only for a brief period. But when a person steadily consumes water faster than the kidneys can excrete it (the maximum urine flow rate is about 15 mL/min) or when renal function is poor, the result may be water intoxication, a state in which excessive body water causes cells to swell dangerously (Figure 27.5). If the body water and Na⁺ lost during blood loss or excessive sweating, vomiting, or diarrhea is replaced by drinking plain water, then body fluids become more dilute. This dilution can cause the Na⁺ concentration of plasma and then of interstitial fluid to fall below the normal range. When the Na⁺ concentration of interstitial fluid decreases, its osmolarity also falls. The net result is osmosis of water from interstitial fluid into the cytosol. Water entering the cells causes them to swell, producing convulsions, coma, and possibly death. To prevent this dire sequence of events in cases of severe electrolyte and water loss, solutions given for intravenous or oral rehydration therapy (ORT) include a small amount of table salt (NaCl).

**CHECKPOINT**

1. What is the approximate volume of each of your body fluid compartments?
2. How are the routes of water gain and loss from the body regulated?
3. By what mechanism does thirst help regulate water intake?
4. How do angiotensin II, aldosterone, atrial natriuretic peptide, and antidiuretic hormone regulate the volume and osmolarity of body fluids?
5. What factors control the movement of water between interstitial fluid and intracellular fluid?

**ELECTROLYTES IN BODY FLUIDS**

**OBJECTIVES**

- Compare the electrolyte composition of the three major fluid compartments: plasma, interstitial fluid, and intracellular fluid.
- Discuss the functions of sodium, chloride, potassium, bicarbonate, calcium, phosphate, and magnesium ions, and explain how their concentrations are regulated.

The ions formed when electrolytes dissolve and dissociate serve four general functions in the body. (1) Because they are largely confined to particular fluid compartments and are more numerous than nonelectrolytes, certain ions control the osmosis of water between fluid compartments. (2) Ions help maintain the acid–base balance required for normal cellular activities. (3) Ions carry electrical current, which allows production of action potentials and graded potentials. (4) Several ions serve as cofactors needed for optimal activity of enzymes.
Concentrations of Electrolytes in Body Fluids

To compare the charge carried by ions in different solutions, the concentration of ions is typically expressed in units of milliequivalents per liter (mEq/liter). These units give the concentration of cations or anions in a given volume of solution. One equivalent is the positive or negative charge equal to the amount of charge in one mole of H⁺; a milliequivalent is one-thousandth of an equivalent. Recall that a mole of a substance is its molecular weight expressed in grams. For ions such as sodium (Na⁺), potassium (K⁺), and bicarbonate (HCO₃⁻), which have a single positive or negative charge, the number of mEq/liter is equal to the number of mmol/liter. For ions such as calcium (Ca²⁺) or phosphate (HPO₄²⁻), which have two positive or negative charges, the number of mEq/liter is twice the number of mmol/liter.

Figure 27.6 compares the concentrations of the main electrolytes and protein anions in blood plasma, interstitial fluid, and intracellular fluid. The chief difference between the two extracellular fluids—blood plasma and interstitial fluid—is that blood plasma contains many protein anions, in contrast to interstitial fluid, which has very few. Because normal capillary membranes are virtually impermeable to proteins, only a few plasma proteins leak out of blood vessels into the interstitial fluid. This difference in protein concentration is largely responsible for the blood colloid osmotic pressure exerted by blood plasma. In other respects, the two fluids are similar.

The electrolyte content of intracellular fluid differs considerably from that of extracellular fluid. In extracellular fluid, the most abundant cation is Na⁺, and the most abundant anion is Cl⁻. In intracellular fluid, the most abundant cation is K⁺, and the most abundant anions are proteins and phosphates (HPO₄²⁻). By actively transporting Na⁺ out of cells and K⁺ into cells, sodium–potassium pumps (Na⁺/K⁺ ATPase) play a major role in maintaining the high intracellular concentration of K⁺ and high extracellular concentration of Na⁺.

Sodium

Sodium ions (Na⁺) are the most abundant ions in extracellular fluid, accounting for 90% of the extracellular cations. The normal blood plasma Na⁺ concentration is 136–148 mEq/liter. As we have already seen, Na⁺ plays a pivotal role in fluid and electrolyte balance because it accounts for almost half of the osmolarity of extracellular fluid (142 of about 300 mOsm/liter). The flow of Na⁺ through voltage-gated channels in the plasma membrane also is necessary for the generation and conduction of action potentials in neurons and muscle fibers. The typical daily intake of Na⁺ in North America often far exceeds the body’s normal daily requirements, due largely to excess dietary salt.

Figure 27.6 Electrolyte and protein anion concentrations in plasma, interstitial fluid, and intracellular fluid. The height of each column represents the milliequivalents per liter (mEq/liter).

The electrolytes present in extracellular fluids are different from those present in intracellular fluid.

What cation and two anions are present in the highest concentrations in ECF and ICF?
The kidneys excrete excess Na+, but they also can conserve it during periods of shortage.

The Na+ level in the blood is controlled by aldosterone, antidiuretic hormone (ADH), and atrial natriuretic peptide (ANP). Aldosterone increases renal reabsorption of Na+. When the blood plasma concentration of Na+ drops below 135 mEq/liter, a condition called hyponatremia, ADH release ceases. The lack of ADH in turn permits greater excretion of water in urine and restoration of the normal Na+ level in ECF. Atrial natriuretic peptide (ANP) increases Na+ excretion by the kidneys when Na+ level is above normal, a condition called hypernatremia.

**CLINICAL CONNECTION Indicators of Na+ Imbalance**

If excess sodium ions remain in the body because the kidneys fail to excrete enough of them, water is also osmotically retained. The result is increased blood volume, increased blood pressure, and edema, an abnormal accumulation of interstitial fluid. Renal failure and hyperaldosteronism (excessive aldosterone secretion) are two causes of Na+ retention. Excessive urinary loss of Na+, by contrast, causes excessive water loss, which results in hypovolemia, an abnormally low blood volume. Hypovolemia related to Na+ loss is most frequently due to the inadequate secretion of aldosterone associated with adrenal insufficiency or overly vigorous therapy with diuretic drugs.

**Chloride**

Chloride ions (Cl−) are the most prevalent anions in extracellular fluid. The normal blood plasma Cl− concentration is 95–105 mEq/liter. Cl− moves relatively easily between the extracellular and intracellular compartments because most plasma membranes contain many Cl− leakage channels and antiporters. For this reason, Cl− can help balance the level of anions in different fluid compartments. One example is the chloride shift that occurs between red blood cells and blood plasma as the blood level of carbon dioxide either increases or decreases (see Figure 23.23 on page 904). In this case, the antiporter exchange of Cl− for HCO3− maintains the correct balance of anions between ECF and ICF. Chloride ions also are part of the hydrochloric acid secreted into gastric juice. ADH helps regulate Cl− balance in body fluids because it governs the extent of water loss in urine. Processes that increase or decrease renal reabsorption of sodium ions also affect reabsorption of chloride ions. (Recall that reabsorption of Na+ and Cl− occurs by means of Na+–Cl− symporters.)

**Potassium**

Potassium ions (K+) are the most abundant cations in intracellular fluid (140 mEq/liter). K+ plays a key role in establishing the resting membrane potential and in the repolarization phase of action potentials in neurons and muscle fibers; K+ also helps maintain normal intracellular fluid volume. When K+ moves into or out of cells, it often is exchanged for H+ and thereby helps regulate the pH of body fluids.

The normal blood plasma K+ concentration is 3.5–5.0 mEq/liter and is controlled mainly by aldosterone. When blood plasma K+ concentration is high, more aldosterone is secreted into the blood. Aldosterone then stimulates principal cells of the renal collecting ducts to secrete more K+ so excess K+ is lost in the urine. Conversely, when blood plasma K+ concentration is low, aldosterone secretion decreases and less K+ is excreted in urine. Because K+ is needed during the repolarization phase of action potentials, abnormal K+ levels can be lethal. For instance, hyperkalemia (above-normal concentration of K+ in blood) can cause death due to ventricular fibrillation.

**Bicarbonate**

Bicarbonate ions (HCO3−) are the second most prevalent extracellular anions. Normal blood plasma HCO3− concentration is 22–26 mEq/liter in systemic arterial blood and 23–27 mEq/liter in systemic venous blood. HCO3− concentration increases as blood flows through systemic capillaries because the carbon dioxide released by metabolically active cells combines with water to form carbonic acid; the carbonic acid then dissociates into H+ and HCO3−. As blood flows through pulmonary capillaries, however, the concentration of HCO3− decreases again as carbon dioxide is exhaled. (Figure 23.23 on page 904 shows these reactions.) Intracellular fluid also contains a small amount of HCO3−. As previously noted, the exchange of Cl− for HCO3− helps maintain the correct balance of anions in extracellular fluid and intracellular fluid.

The kidneys are the main regulators of blood HCO3− concentration. The intercalated cells of the renal tubule can either form HCO3− and release it into the blood when the blood level is low (see Figure 27.8) or excrete excess HCO3− in the urine when the level in blood is too high. Changes in the blood level of HCO3− are considered later in this chapter in the section on acid–base balance.

**Calcium**

Because such a large amount of calcium is stored in bone, it is the most abundant mineral in the body. About 98% of the calcium in adults is located in the skeleton and teeth, where it is combined with phosphates to form a crystal lattice of mineral salts. In body fluids, calcium is mainly an extracellular cation (Ca2+). The normal concentration of free or unattached Ca2+ in blood plasma is 4.5–5.5 mEq/liter. About the same amount of Ca2+ is attached to various plasma proteins. Besides contributing to the hardness of bones and teeth, Ca2+ plays important roles in blood clotting, neurotransmitter release, maintenance of muscle tone, and excitability of nervous and muscle tissue.

The most important regulator of Ca2+ concentration in blood plasma is parathyroid hormone (PTH) (see Figure 18.14 on page 664). A low level of Ca2+ in blood plasma promotes release of more PTH, which stimulates osteoclasts in bone tissue to release calcium (and phosphate) from bone extracellular matrix. Thus, PTH increases bone resorption. Parathyroid hormone also enhances reabsorption of Ca2+ from glomerular filtrate through re-
nal tubule cells and back into blood, and increases production of calcitriol (the form of vitamin D that acts as a hormone), which in turn increases \( \text{Ca}^{2+} \) absorption from food in the gastrointestinal tract. Recall that calcitonin (CT) produced by the thyroid gland inhibits the activity of osteoclasts, accelerates \( \text{Ca}^{2+} \) deposition into bones, and thus lowers blood \( \text{Ca}^{2+} \) levels.

### Phosphate

About 85% of the phosphate in adults is present as calcium phosphate salts, which are structural components of bone and teeth. The remaining 15% is ionized. Three phosphate ions \( (\text{H}_2\text{PO}_4^-, \text{HPO}_4^{2-}, \text{and} \text{PO}_4^{3-}) \) are important intracellular anions. At the normal pH of body fluids, \( \text{HPO}_4^{2-} \) is the most prevalent form. Phosphates contribute about 100 mEq/liter of anions to intracellular fluid. \( \text{HPO}_4^{2-} \) is an important buffer of \( \text{H}^+ \), both in body fluids and in the urine. Although some are “free,” most phosphate ions are covalently bound to organic molecules such as lipids (phospholipids), proteins, carbohydrates, nucleic acids (DNA and RNA), and adenosine triphosphate (ATP).

The normal blood plasma concentration of ionized phosphate is only 1.7–2.6 mEq/liter. The same two hormones that govern calcium homeostasis—parathyroid hormone (PTH) and calcitriol—also regulate the level of \( \text{HPO}_4^{2-} \) in blood plasma. PTH stimulates resorption of bone extracellular matrix by osteoclasts, which releases both phosphate and calcium ions into the bloodstream. In the kidneys, however, PTH inhibits reabsorption of phosphate ions while stimulating reabsorption of calcium ions by renal tubular cells. Thus, PTH increases urinary excretion of phosphate and lowers blood phosphate level. Calcitriol promotes absorption of both phosphates and calcium from the gastrointestinal tract. Fibroblast growth factor 23 (FGF 23) is a polypeptide paracrine (local hormone) that also helps regulate blood plasma levels of \( \text{HPO}_4^{2-} \). This hormone decreases \( \text{HPO}_4^{2-} \) blood levels by increasing \( \text{HPO}_4^{2-} \) excretion by the kidneys and decreasing absorption of \( \text{HPO}_4^{2-} \) by the gastrointestinal tract.

### Magnesium

In adults, about 54% of the total body magnesium is part of bone phosphate salts as magnesium ions. The remaining 46% occurs as magnesium ions \( (\text{Mg}^{2+}) \) in intracellular fluid (45%) and extracellular fluid (1%). \( \text{Mg}^{2+} \) is the second most common intracellular cation (35 mEq/liter). Functionally, \( \text{Mg}^{2+} \) is a cofactor for certain enzymes needed for the metabolism of carbohydrates and proteins and for the sodium–potassium pump. \( \text{Mg}^{2+} \) is essential for normal neuromuscular activity, synaptic transmission, and myocardial functioning. In addition, secretion of parathyroid hormone (PTH) depends on \( \text{Mg}^{2+} \).

Normal blood plasma \( \text{Mg}^{2+} \) concentration is low, only 1.3–2.1 mEq/liter. Several factors regulate the blood plasma level of \( \text{Mg}^{2+} \) by varying the rate at which it is excreted in the urine. The kidneys increase urinary excretion of \( \text{Mg}^{2+} \) in response to hypercalcemia, hypermagnesemia, increases in extracellular fluid volume, decreases in parathyroid hormone, and acidosis. The opposite conditions decrease renal excretion of \( \text{Mg}^{2+} \).

Table 27.2 describes the imbalances that result from the deficiency or excess of several electrolytes.

People at risk for fluid and electrolyte imbalances include those who depend on others for fluid and food, such as infants, the elderly, and the hospitalized; individuals undergoing medical treatment that involves intravenous infusions, drainages or sucktions, and urinary catheters; and people who receive diuretics, experience excessive fluid losses and require increased fluid intake, or experience fluid retention and have fluid restrictions. Finally, athletes and military personnel in extremely hot environments, postoperative individuals, severe burn or trauma cases, individuals with chronic diseases (congestive heart failure, diabetes, chronic obstructive lung disease, and cancer), people in confinement, and individuals with altered levels of consciousness who may be unable to communicate needs or respond to thirst are also subject to fluid and electrolyte imbalances.

#### CHECKPOINT

6. What are the functions of electrolytes in the body?
7. Name three important extracellular electrolytes and three important intracellular electrolytes and indicate how each is regulated.

### ACID–BASE BALANCE

#### OBJECTIVES

- Compare the roles of buffers, exhalation of carbon dioxide, and kidney excretion of \( \text{H}^+ \) in maintaining pH of body fluids.
- Define acid–base imbalances, describe their effects on the body, and explain how they are treated.

From our discussion thus far, it should be clear that various ions play different roles that help maintain homeostasis. A major homeostatic challenge is keeping the \( \text{H}^+ \) concentration \((\text{pH})\) of body fluids at an appropriate level. This task—the maintenance of acid–base balance—is of critical importance to normal cellular function. For example, the three-dimensional shape of all body proteins, which enables them to perform specific functions, is very sensitive to \( \text{pH} \) changes. When the diet contains a large amount of protein, as is typical in North America, cellular metabolism produces more acids than bases, which tends to acidify the blood. Before proceeding with this section of the chapter, you may wish to review the discussion of acids, bases, and \( \text{pH} \) on pages 41–43.

In a healthy person, several mechanisms help maintain the \( \text{pH} \) of systemic arterial blood between 7.35 and 7.45. (A \( \text{pH} \) of 7.4 corresponds to a \( \text{H}^+ \) concentration of 0.00004 mEq/liter = 40 nEq/liter.) Because metabolic reactions often produce a huge excess of \( \text{H}^+ \), the lack of any mechanism for the disposal of \( \text{H}^+ \) would cause \( \text{H}^+ \) level in body fluids to rise quickly to a lethal level. Homeostasis of \( \text{H}^+ \) concentration within a narrow range is thus essential to survival. The removal of \( \text{H}^+ \) from body fluids and its subsequent elimination from the body depend on the following three major mechanisms:
TABLE 27.2

Blood Electrolyte Imbalances

<td>Sodium (Na⁺)</td>
<td>Hyponatremia (hi pó-ná-TRE-mé-a) may be due to decreased sodium intake; increased sodium loss through vomiting, diarrhea, aldosterone deficiency, or taking certain diuretics; and excessive water intake.</td>
<td>Muscular weakness; dizziness, headache, and hypotension; tachycardia and shock; mental confusion, stupor, and coma.</td>
<td>Hypernatremia may occur with dehydration, water deprivation, or excessive sodium in diet or intravenous fluids; causes hypertonicity of ECF, which pulls water out of body cells into ECF, causing cellular dehydration.</td>
<td>Intense thirst, hypertension, edema, agitation, and convulsions.</td>
</tr>
<tr>
<td>Chloride (Cl⁻)</td>
<td>Hypochloremia (hi pó-klo-RE-mé-a) may be due to excessive vomiting, overhydration, aldosterone deficiency, congestive heart failure, and therapy with certain diuretics such as furosemide (Lasix®).</td>
<td>Muscle spasms, metabolic alkalosis, shallow respirations, hypotension, and tetany.</td>
<td>Hyperchloremia may result from dehydration due to water loss or water deprivation; excessive chloride intake; or severe renal failure, hyperaldosteronism, certain types of acidosis, and some drugs.</td>
<td>Lethargy, weakness, metabolic acidosis, and rapid, deep breathing.</td>
</tr>
<tr>
<td>Potassium (K⁺)</td>
<td>Hypokalemia (hi pó-ka-lÉ-mé-a) may result from excessive loss due to vomiting or diarrhea, decreased potassium intake, hyperaldosteronism, kidney disease, and therapy with some diuretics.</td>
<td>Muscle fatigue, flaccid paralysis, mental confusion, increased urine output, shallow respirations, and changes in the electrocardiogram, including flattening of the T wave.</td>
<td>Hyperkalemia may be due to excessive potassium intake, renal failure, aldosterone deficiency, crushing injuries to body tissues, or transfusion of hemolyzed blood.</td>
<td>Irritability, nausea, vomiting, diarrhea, muscular weakness; can cause death by inducing ventricular fibrillation.</td>
</tr>
<tr>
<td>Calcium (Ca²⁺)</td>
<td>Hypocalcemia (hi pohl-se-é-mé-a) may be due to increased calcium loss, reduced calcium intake, elevated levels of phosphate, or hypoparathyroidism.</td>
<td>Numbness and tingling of the fingers; hyperactive reflexes, muscle cramps, tetany, and convulsions; bone fractures; spasms of laryngeal muscles that can cause death by asphyxiation.</td>
<td>Hypercalcemia may result from hyperparathyroidism, some cancers, excessive intake of vitamin D, and Paget’s disease of bone.</td>
<td>Lethargy, weakness, anorexia, nausea, vomiting, polyuria, itching, bone pain, depression, confusion, paresthesia, stupor, and coma.</td>
</tr>
<tr>
<td>Phosphate (HPO₄²⁻)</td>
<td>Hypophosphatemia (hi pó-fos-a-TÉ-mé-a) may occur through increased urinary losses, decreased intestinal absorption, or increased utilization.</td>
<td>Confusion, seizures, coma, chest and muscle pain, numbness and tingling of the fingers, decreased coordination, memory loss, and lethargy.</td>
<td>Hyperphosphatemia occurs when the kidneys fail to excrete excess phosphate, as happens in renal failure; can also result from increased intake of phosphates or destruction of body cells, which releases phosphates into the blood.</td>
<td>Anorexia, nausea, vomiting, muscular weakness, hyperactive reflexes, tetany, and tachycardia.</td>
</tr>
<tr>
<td>Magnesium (Mg²⁺)</td>
<td>Hypomagnesemia (hi pó-mag-NE-SÉ-mé-a) may be due to inadequate intake or excessive loss in urine or feces; also occurs in alcoholism, malnutrition, diabetes mellitus, and diuretic therapy.</td>
<td>Weakness, irritability, tetany, delirium, convulsions, confusion, anorexia, nausea, vomiting, paresthesia, and cardiac arrhythmias.</td>
<td>Hypermagnesemia occurs in renal failure or due to increased intake of Mg²⁺, such as Mg²⁺-containing antacids; also occurs in aldosterone deficiency and hypothyroidism.</td>
<td>Hypotension, muscular weakness or paralysis, anorexia, vomiting, and altered mental functioning.</td>

*Values are normal ranges of blood plasma levels in adults.
1. Buffer systems. Buffers act quickly to temporarily bind \( H^+ \), removing the highly reactive, excess \( H^+ \) from solution. Buffers thus raise pH of body fluids but do not remove \( H^+ \) from the body.

2. Exhalation of carbon dioxide. By increasing the rate and depth of breathing, more carbon dioxide can be exhaled. Within minutes this reduces the level of carbonic acid in blood, which raises the blood pH (reduces blood \( H^+ \) level).

3. Kidney excretion of \( H^+ \). The slowest mechanism, but the only way to eliminate acids other than carbonic acid, is through their excretion in urine.

We will examine each of these mechanisms in more detail in the following sections.

The Actions of Buffer Systems

Most buffer systems in the body consist of a weak acid and the salt of that acid, which functions as a weak base. Buffers prevent rapid, drastic changes in the pH of body fluids by converting strong acids and bases into weak acids and weak bases within fractions of a second. Strong acids lower pH more than weak acids because strong acids release \( H^+ \) more readily and thus contribute more free hydrogen ions. Similarly, strong bases raise pH more than weak ones. The principal buffer systems of the body fluids are the protein buffer system, the carboxylic acid–bicarbonate buffer system, and the phosphate buffer system.

Protein Buffer System

The protein buffer system is the most abundant buffer in intracellular fluid and blood plasma. For example, the protein hemoglobin is an especially good buffer within red blood cells, and albumin is the main protein buffer in blood plasma. Proteins are composed of amino acids, organic molecules that contain at least one carboxyl group (–COOH) and at least one amino group (–NH₂); these groups are the functional components of the protein buffer system. The free carboxyl group at one end of a protein acts like an acid by releasing \( H^+ \) when pH rises; it dissociates as follows:

\[
\text{NH}_2-C-COOH \rightarrow \text{NH}_2-C-COO^- + H^+ \\
\text{H} \quad \text{H}
\]

The \( H^+ \) is then able to react with any excess \( OH^- \) in the solution to form water. The free amino group at the other end of a protein can act as a base by combining with \( H^+ \) when pH falls, as follows:

\[
\text{NH}_2-C-COOH + H^+ \rightarrow \text{NH}_3-C-COOH \\
\text{H} \quad \text{H}
\]

So proteins can buffer both acids and bases. In addition to the terminal carboxyl and amino groups, side chains that can buffer \( H^+ \) are present on seven of the 20 amino acids.

As we have already noted, the protein hemoglobin is an important buffer of \( H^+ \) in red blood cells (see Figure 23.23 on page 904). As blood flows through the systemic capillaries, carbon dioxide (CO₂) passes from tissue cells into red blood cells, where it combines with water (H₂O) to form carbonic acid (H₂CO₃). Once formed, H₂CO₃ dissociates into \( H^+ \) and HCO₃⁻. At the same time that CO₂ is entering red blood cells, oxyhemoglobin (Hb—O₂) is giving up its oxygen to tissue cells. Reduced hemoglobin (deoxyhemoglobin) picks up most of the \( H^+ \). For this reason, reduced hemoglobin usually is written as Hb—H.

The following reactions summarize these relations:

\[
\begin{align*}
\text{H}_2\text{O} + \text{CO}_2 & \rightarrow \text{H}_2\text{CO}_3 \\
\text{H}_2\text{CO}_3 & \rightarrow \text{H}^+ + \text{HCO}_3^- \\
\text{Hb—O}_2 + \text{H}^+ & \rightarrow \text{Hb—H} + \text{O}_2 \\
\end{align*}
\]

Carbonic Acid–Bicarbonate Buffer System

The carbonic acid–bicarbonate buffer system is based on the bicarbonate ion (HCO₃⁻), which can act as a weak base, and carbonic acid (H₂CO₃), which can act as a weak acid. As you have already learned, HCO₃⁻ is a significant anion in both intracellular and extracellular fluids (see Figure 27.6). Because the kidneys also synthesize new HCO₃⁻ and reabsorb filtered HCO₃⁻, this important buffer is not lost in the urine. If there is an excess of \( H^+ \), the HCO₃⁻ can function as a weak base and remove the excess \( H^+ \) as follows:

\[
\text{H}^+ + \text{HCO}_3^- \rightarrow \text{H}_2\text{CO}_3
\]

Then, H₂CO₃ dissociates into water and carbon dioxide, and the CO₂ is exhaled from the lungs.

Conversely, if there is a shortage of \( H^+ \), the H₂CO₃ can function as a weak acid and provide \( H^+ \) as follows:

\[
\text{H}_2\text{CO}_3 \rightarrow \text{H}^+ + \text{HCO}_3^-
\]

At a pH of 7.4, HCO₃⁻ concentration is about 24 mEq/liter and H₂CO₃ concentration is about 1.2 mmol/liter, so bicarbonate ions outnumber carbonic acid molecules by 20 to 1. Because CO₂ and H₂O combine to form H₂CO₃, this buffer system cannot protect against pH changes due to respiratory problems in which there is an excess or shortage of CO₂.

Phosphate Buffer System

The phosphate buffer system acts via a mechanism similar to the one for the carbonic acid–bicarbonate buffer system. The components of the phosphate buffer system are the ions dihydrogen phosphate (H₂PO₄⁻) and monohydrogen phosphate (HPO₄²⁻). Recall that phosphates are major anions in intracellu-
The diaphragm contracts more forcefully and frequently so more CO₂ is exhaled. As less H₂CO₃ forms and fewer H+ are present, blood pH increases (H+ concentration decreases).

As less H₂CO₃ forms and fewer H+ are present, blood pH increases (H+ concentration decreases)

If you hold your breath for 30 seconds, what is likely to happen to your blood pH?

Exhalation of Carbon Dioxide

The simple act of breathing also plays an important role in maintaining the pH of body fluids. An increase in the carbon dioxide (CO₂) concentration in body fluids increases H+ concentration and thus lowers the pH (makes body fluids more acidic). Because H₂CO₃ can be eliminated by exhaling CO₂, it is called a volatile acid. Conversely, a decrease in the CO₂ concentration of body fluids raises the pH (makes body fluids more alkaline). This chemical interaction is illustrated by the following reversible reactions:

\[
\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-
\]

Changes in the rate and depth of breathing can alter the pH of body fluids within a couple of minutes. With increased ventilation, more CO₂ is exhaled. When CO₂ levels decrease, the reaction is driven to the left (blue arrows), H+ concentration falls, and blood pH increases. Doubling the ventilation increases pH by about 0.23 units, from 7.4 to 7.63. If ventilation is slower than normal, less carbon dioxide is exhaled. When CO₂ levels increase, the reaction is driven to the right (red arrows), the H+ concentration increases, and blood pH decreases. Reducing ventilation to one-quarter of normal lowers the pH by 0.4 units, from 7.4 to 7.0. These examples show the powerful effect of alterations in breathing on the pH of body fluids.

The pH of body fluids and the rate and depth of breathing interact via a negative feedback loop (Figure 27.7). When the blood acidity increases, the decrease in pH (increase in concentration of H+) is detected by central chemoreceptors in the medulla oblongata and peripheral chemoreceptors in the aortic
and carotid bodies, both of which stimulate the inspiratory area in the medulla oblongata. As a result, the diaphragm and other respiratory muscles contract more forcefully and frequently, so more CO₂ is exhaled. As less H₂CO₃ forms and fewer H⁺ are present, blood pH increases. When the response brings blood pH (H⁺ concentration) back to normal, there is a return to acid–base homeostasis. The same negative feedback loop operates if the blood level of CO₂ increases. Ventilation increases, which removes more CO₂, reducing the H⁺ concentration and increasing the blood’s pH.

By contrast, if the pH of the blood increases, the respiratory center is inhibited and the rate and depth of breathing decreases. A decrease in the CO₂ concentration of the blood has the same effect. When breathing decreases, CO₂ accumulates in the blood so its H⁺ concentration increases.

Kidney Excretion of H⁺

Metabolic reactions produce nonvolatile acids such as sulfuric acid at a rate of about 1 mEq of H⁺ per day for every kilogram of body mass. The only way to eliminate this huge acid load is to excrete H⁺ in the urine. Given the magnitude of these contributions to acid–base balance, it’s not surprising that renal failure can quickly cause death.

As you learned in Chapter 26, cells in both the proximal convoluted tubules (PCT) and the collecting ducts of the kidneys secrete hydrogen ions into the tubular fluid. In the PCT, Na⁺/H⁺ antiporters secrete H⁺ as they reabsorb Na⁺ (see Figure 26.13 on page 1037). Even more important for regulation of pH of body fluids, however, are the intercalated cells of the collecting duct. The apical membranes of some intercalated cells include proton pumps (H⁺ ATPases) that secrete H⁺ into the tubular fluid (Figure 27.8). Intercalated cells can secrete H⁺ against a concentration gradient so effectively that urine can be up to 1000 times (3 pH units) more acidic than blood. HCO₃⁻ produced by dissociation of H₂CO₃ inside intercalated cells crosses the basolateral membrane by means of Cl⁻/HCO₃⁻ antiporters and then diffuses into peritubular capillaries (Figure 27.8a). The HCO₃⁻ that enters the blood in this way is new (not filtered). For this reason, blood leaving the kidney in the renal vein may have a higher HCO₃⁻ concentration than blood entering the kidney in the renal artery.

Interestingly, a second type of intercalated cell has proton pumps in its basolateral membrane and Cl⁻/HCO₃⁻ antiporters in its apical membrane. These intercalated cells secrete HCO₃⁻ and reabsorb H⁺. Thus, the two types of intercalated cells help maintain the pH of body fluids in two ways—by excreting excess H⁺ when pH of body fluids is too low and by excreting excess HCO₃⁻ when pH is too high.

Some H⁺ secreted into the tubular fluid of the collecting duct are buffered, but not by HCO₃⁻, most of which has been filtered and reabsorbed. Two other buffers combine with H⁺ in the collecting duct (Figure 27.8b). The most plentiful buffer in the tubular fluid of the collecting duct is HPO₄²⁻ (monohydrogen phosphate ion). In addition, a small amount of NH₃ (ammonia)
Compensation may be either acid–base imbalance that acts to normalize arterial blood pH. Within the normal range, or alkalosis, be countered by disorders and death. Acidosis usually die while in a coma. A major physiological effect of acidosis is depression of the central nervous system through depression of synaptic transmission. If the systemic arterial blood pH falls below 7, depression of the nervous system is so severe that the individual becomes disoriented, then comatose, and may die. Patients with severe acidosis usually die while in a coma. A major physiological effect of alkalosis, by contrast, is overexcitability in both the central nervous system and peripheral nerves. Neurons conduct impulses repetitively, even when not stimulated by normal stimuli; the results are nervousness, muscle spasms, and even convulsions and death.

A change in blood pH that leads to acidosis or alkalosis may be countered by compensation, the physiological response to an acid–base imbalance that acts to normalize arterial blood pH. Compensation may be either complete, if pH indeed is brought within the normal range, or partial, if systemic arterial blood pH is still lower than 7.35 or higher than 7.45. If a person has altered blood pH due to metabolic causes, hyperventilation or hypoventilation can help bring blood pH back toward the normal range; this form of compensation, termed respiratory compensation, occurs within minutes and reaches its maximum within hours. If, however, a person has altered blood pH due to respiratory causes, then renal compensation—changes in secretion of H+ and reabsorption of HCO3− by the kidney tubules—can help reverse the change. Renal compensation may begin in minutes, but it takes days to reach maximum effectiveness.

In the discussion that follows, note that both respiratory acidosis and respiratory alkalosis are disorders resulting from changes in the partial pressure of CO2 (PCO2) in systemic arterial blood (normal range is 35–45 mmHg). By contrast, both metabolic acidosis and metabolic alkalosis are disorders resulting from changes in HCO3− concentration (normal range is 22–26 mEq/liter in systemic arterial blood).

**Respiratory Acidosis**

The hallmark of respiratory acidosis is an abnormally high PCO2 in systemic arterial blood—above 45 mmHg. Inadequate exhalation of CO2 causes the blood pH to drop. Any condition that decreases the movement of CO2 from the blood to the alveoli of the lungs to the atmosphere causes a buildup of CO2, H2CO3, and H+. Such conditions include emphysema, pulmonary edema, injury to the respiratory center of the medulla oblongata, airway obstruction, or disorders of the muscles involved in breathing. If the respiratory problem is not too severe, the kidneys can help raise the blood pH into the normal range by increasing excretion of H+ and reabsorption of HCO3− (renal compensation). The goal in treatment of respiratory acidosis is to increase the exhalation of CO2 as, for instance, by providing ventilation therapy. In addition, intravenous administration of HCO3− may be helpful.

**Respiratory Alkalosis**

In respiratory alkalosis, systemic arterial blood PCO2 falls below 35 mmHg. The cause of the drop in PCO2 and the resulting increase in pH is hyperventilation, which occurs in conditions that stimulate the inspiratory area in the brain stem. Such conditions include oxygen deficiency due to high altitude or pulmonary disease, cerebrovascular accident (stroke), or severe anxiety. Again, renal compensation may bring blood pH into the normal range if the kidneys are able to decrease excretion of H+ and reabsorption of HCO3−. Treatment of respiratory alkalosis is aimed at increasing the level of CO2 in the body. One simple treatment is to have the person inhale and exhale into a paper bag for a short period; as a result, the person inhales air containing a higher-than-normal concentration of CO2.

**Metabolic Acidosis**

In metabolic acidosis, the systemic arterial blood HCO3− level drops below 22 mEq/liter. Such a decline in this important buffer causes the blood pH to decrease. Three situations may lower the blood level of HCO3−: (1) actual loss of HCO3−, such as

may occur with severe diarrhea or renal dysfunction; (2) accumulation of an acid other than carbonic acid, as may occur in ketosis (described on page 993); or (3) failure of the kidneys to excrete H\(^+\) from metabolism of dietary proteins. If the problem is not too severe, hyperventilation can help bring blood pH into the normal range (respiratory compensation). Treatment of metabolic acidosis consists of administering intravenous solutions of sodium bicarbonate and correcting the cause of the acidosis.

**Metabolic Alkalosis**

In **metabolic alkalosis**, the systemic arterial blood HCO\(_3^-\) concentration is above 26 mEq/liter. A nonrespiratory loss of acid or excessive intake of alkaline drugs causes the blood pH to increase above 7.45. Excessive vomiting of gastric contents, which results in a substantial loss of hydrochloric acid, is probably the most frequent cause of metabolic alkalosis. Other causes include gastric suctioning, use of certain diuretics, endocrine disorders, excessive intake of alkaline drugs (antacids), and severe dehydration. Respiratory compensation through hyperventilation may bring blood pH into the normal range. Treatment of metabolic alkalosis consists of giving fluid solutions to correct Cl\(^-\), K\(^+\), and other electrolyte deficiencies plus correcting the cause of alkalosis.

**CHECKPOINT**

8. Explain how each of the following buffer systems helps to maintain the pH of body fluids: proteins, carbonic acid–bicarbonate buffers, and phosphates.

10. What are the principal physiological effects of acidosis and alkalosis?
AGING AND FLUID, ELECTROLYTE, AND ACID–BASE BALANCE

OBJECTIVE

- Describe the changes in fluid, electrolyte, and acid–base balance that may occur with aging.

There are significant differences between adults and infants, especially premature infants, with respect to fluid distribution, regulation of fluid and electrolyte balance, and acid–base homeostasis. Accordingly, infants experience more problems than adults in these areas. The differences are related to the following conditions:

- **Proportion and distribution of water.** A newborn’s total body mass is about 75% water (and can be as high as 90% in a premature infant); an adult’s total body mass is about 55–60% water. (The “adult” percentage is achieved at about 2 years of age.) Adults have twice as much water in ICF as ECF, but the opposite is true in premature infants. Because ECF is subject to more changes than ICF, rapid losses or gains of body water are much more critical in infants. Given that the rate of fluid intake and output is about seven times higher in infants than in adults, the slightest changes in fluid balance can result in severe abnormalities.

- **Metabolic rate.** The metabolic rate of infants is about double that of adults. This results in the production of more metabolic wastes and acids, which can lead to the development of acidosis in infants.

- **Functional development of the kidneys.** Infant kidneys are only about half as efficient in concentrating urine as those of adults. (Functional development is not complete until close to the end of the first month after birth.) As a result, the kidneys of newborns can neither concentrate urine nor rid the body of excess acids as effectively as those of adults.

- **Body surface area.** The ratio of body surface area to body volume of infants is about three times greater than that of adults. Water loss through the skin is significantly higher in infants than in adults.

- **Breathing rate.** The higher breathing rate of infants (about 30 to 80 times a minute) causes greater water loss from the lungs. Respiratory alkalosis may occur because greater ventilation eliminates more CO₂ and lowers the P\(_{\text{CO}_2}\).

- **Ion concentrations.** Newborns have higher K\(^+\) and Cl\(^-\) concentrations than adults. This creates a tendency toward metabolic acidosis.

By comparison with children and younger adults, older adults often have an impaired ability to maintain fluid, electrolyte, and acid–base balance. With increasing age, many people have a decreased volume of intracellular fluid and decreased total body K\(^+\) due to declining skeletal muscle mass and increasing mass of adipose tissue (which contains very little water). Age-related decreases in respiratory and renal functioning may compromise acid–base balance by slowing the exhalation of CO₂ and the excretion of excess acids in urine. Other kidney changes, such as decreased blood flow, decreased glomerular filtration rate, and reduced sensitivity to antidiuretic hormone, have an adverse effect on the ability to maintain fluid and electrolyte balance. Due to a decrease in the number and efficiency of sweat glands, water loss from the skin decreases with age. Because of these age-related changes, older adults are susceptible to several fluid and electrolyte disorders:

- **Dehydration and hypernatremia** often occur due to inadequate fluid intake or loss of more water than Na\(^+\) in vomit, feces, or urine.

- **Hypokalemia** may occur due to inadequate intake of Na\(^+\); elevated loss of Na\(^+\) in urine, vomit, or diarrhea; or impaired ability of the kidneys to produce dilute urine.

- **Hypokalemia** often occurs in older adults who chronically use laxatives to relieve constipation or who take K\(^+\)-depleting diuretic drugs for treatment of hypertension or heart disease.

- **Acidosis** may occur due to impaired ability of the lungs and kidneys to compensate for acid–base imbalances. One cause of acidosis is decreased production of ammonia (NH₃) by renal tubule cells, which then is not available to combine with H\(^+\) and be excreted in urine as NH₄\(^+\); another cause is reduced exhalation of CO₂.

CHECKPOINT

11. Why do infants experience greater problems with fluid, electrolyte, and acid–base balance than adults?

STUDY OUTLINE

Fluid Compartments and Fluid Balance (p. 1063)

1. Body fluid includes water and dissolved solutes.

2. About two-thirds of the body’s fluid is located within cells and is called intracellular fluid (ICF). The other one-third, called extracellular fluid (ECF), includes interstitial fluid; blood plasma and lymph; cerebrospinal fluid; gastrointestinal tract fluids; synovial fluid; fluids of the eyes and ears; pleural, pericardial, and peritoneal fluids; and glomerular filtrate.

3. Fluid balance means that the required amounts of water and solutes are present and are correctly proportioned among the various compartments.

4. An inorganic substance that dissociates into ions in solution is called an electrolyte.

5. Water is the largest single constituent in the body. It makes up 45–75% of total body mass, depending on age, gender, and the amount of adipose tissue present.
6. Daily water gain and loss are each about 2500 mL. Sources of water gain are ingested liquids and foods, and water produced by cellular respiration and dehydration synthesis reactions (metabolic water). Water is lost from the body via urination, evaporation from the skin surface, exhalation of water vapor, and defecation. In women, menstrual flow is an additional route for loss of body water.

7. Body water gain is regulated by adjusting the volume of water intake, mainly by drinking more or less fluid. The thirst center in the hypothalamus governs the urge to drink.

8. Although increased amounts of water and solutes are lost through sweating and exhalation during exercise, loss of excess body water or excess solutes depends mainly on regulating excretion in the urine. The extent of urinary NaCl loss is the main determinant of body fluid volume; the extent of urinary water loss is the main determinant of body fluid osmolarity.

9. Table 27.1 on page 1066 summarizes the factors that regulate water gain and water loss in the body.

10. Angiotensin II and aldosterone reduce urinary loss of Na" and Cl" and thereby increase the volume of body fluids. ANP promotes natriuresis, elevated excretion of Na" (and Cl"), which decreases blood volume.

11. The major hormone that regulates water loss and thus body fluid osmolarity is antidiuretic hormone (ADH).

12. An increase in the osmolarity of interstitial fluid draws water out of cells, and they shrink slightly. A decrease in the osmolarity of interstitial fluid causes cells to swell. Most often a change in osmolarity is due to a change in the concentration of Na", the dominant solute in interstitial fluid.

13. When a person consumes water faster than the kidneys can excrete it or when renal function is poor, the result may be water intoxication, in which cells swell dangerously.

**Electrolytes in Body Fluids (p. 1067)**

1. Ions formed when electrolytes dissolve in body fluids control the osmosis of water between fluid compartments, help maintain acid–base balance, and carry electrical current.

2. The concentrations of cations and anions are expressed in units of milliequivalents/liter (mEq/liter).

3. Blood plasma, interstitial fluid, and intracellular fluid contain varying types and amounts of ions.

4. Sodium ions (Na") are the most abundant extracellular ions. They are involved in impulse transmission, muscle contraction, and fluid and electrolyte balance. Na" level is controlled by aldosterone, antidiuretic hormone, and atrial natriuretic peptide.

5. Chloride ions (Cl") are the major extracellular anions. They play a role in regulating osmotic pressure and forming HCl in gastric juice. Cl" level is controlled indirectly by antidiuretic hormone and by processes that increase or decrease renal reabsorption of Na".

6. Potassium ions (K") are the most abundant cations in intracellular fluid. They play a key role in the resting membrane potential and action potential of neurons and muscle fibers; help maintain intracellular fluid volume; and contribute to regulation of pH. K" level is controlled by aldosterone.

7. Bicarbonate ions (HCO3") are the second most abundant anions in extracellular fluid. They are the most important buffer in blood plasma.

8. Calcium is the most abundant mineral in the body. Calcium salts are structural components of bones and teeth. Ca"", which are principally extracellular cations, function in blood clotting, neurotransmitter release, and contraction of muscle. Ca"" level is controlled mainly by parathyroid hormone and calcitriol.

9. Phosphate ions (H3PO4", H2PO4"", and PO4""') principally intracellular anions, and their salts are structural components of bones and teeth. They are also required for the synthesis of nucleic acids and ATP and participate in buffer reactions. Their level is controlled by parathyroid hormone and calcitriol.

10. Magnesium ions (Mg2") are primarily intracellular cations. They act as cofactors in several enzyme systems.

11. Table 27.2 on page 1071 describes the imbalances that result from deficiency or excess of important body electrolytes.

**Acid–Base Balance (p. 1070)**

1. The overall acid–base balance of the body is maintained by controlling the H" concentration of body fluids, especially extracellular fluid.

2. The normal pH of systemic arterial blood is 7.35–7.45.

3. Homeostasis of pH is maintained by buffer systems, via exhalation of carbon dioxide, and via kidney excretion of H" and reabsorption of HCO3".

4. The important buffer systems include proteins, carbonic acid–bicarbonate buffers, and phosphates.

5. An increase in exhalation of carbon dioxide increases blood pH; a decrease in exhalation of CO2 decreases blood pH.

6. In the proximal convoluted tubules of the kidneys, Na"/H+ antiporters secrete H" as they reabsorb Na". In the collecting ducts of the kidneys, some intercalated cells reabsorb K" and HCO3" and secrete H"; other intercalated cells secrete HCO3". In these ways, the kidneys can increase or decrease the pH of body fluids.

7. Table 27.3 on page 1075 summarizes the mechanisms that maintain pH of body fluids.

8. Acidosis is a systemic arterial blood pH below 7.35; its principal effect is depression of the central nervous system (CNS). Alkalosis is a systemic arterial blood pH above 7.45; its principal effect is overexcitability of the CNS.

9. Respiratory acidosis and alkalosis are disorders due to changes in blood P CO2; metabolic acidosis and alkalosis are disorders associated with changes in blood HCO3" concentration.

10. Metabolic acidosis or alkalosis can be compensated by respiratory mechanisms (respiratory compensation); respiratory acidosis or alkalosis can be compensated by renal mechanisms (renal compensation).

11. Table 27.4 on page 1076 summarizes the effects of respiratory and metabolic acidosis and alkalosis.

12. By examining systemic arterial blood pH, HCO3", and P CO2 values, it is possible to pinpoint the cause of an acid–base imbalance.

**Aging and Fluid, Electrolyte, and Acid–Base Balance (p. 1077)**

1. With increasing age, there is decreased intracellular fluid volume and decreased K" due to declining skeletal muscle mass.

2. Decreased kidney function with aging adversely affects fluid and electrolyte balance.
1. The source of water that is derived from aerobic cellular respiration and dehydration synthesis reactions is ____ water.

2. In the carbonic acid–bicarbonate buffer system, the ____ acts as a weak base, and ____ acts as a weak acid.

Indicate whether the following statements are true or false.

3. The phosphate buffer system is an important regulator of pH in the cytosol.

4. The two compartments in which water can be found are plasma and cytosol.

Choose the one best answer to the following questions.

5. The primary means of regulating body water gain is adjusting (a) the volume of water intake. (b) the rate of cellular respiration. (c) the formation of metabolic water. (d) the volume of metabolic water. (e) the metabolic use of water.

6. Which of the following stimulate thirst? (1) a decreased production of saliva, (2) a decrease in nerve impulses from hypothalamic osmoreceptors, (3) an increase in osmolarity of body fluids, (4) angiotensin II release, (5) release of atrial natriuretic peptide, (6) an increase in blood volume.

(a) 1, 2, 4, and 6 (b) 1, 3, 5, and 6 (c) 1, 3, and 4 (d) 2, 4, and 6 (e) 1, 4, 5, and 6

7. Which of the following is not true concerning the protein buffer system? (a) Albumin is considered the main protein buffer in blood plasma. (b) Albumin is the most abundant buffer in blood plasma and intracellular fluid. (c) The functional components of a protein buffer system are the carboxyl group and the amino group. (d) Protein buffers are the primary buffers of acids in urine. (e) Proteins can buffer both acids and bases.

8. Which of the following statements are true? (1) Buffers prevent rapid, drastic changes in pH of a body fluid. (2) Buffers work slowly. (3) Strong acids lower pH more than weak acids because strong acids contribute fewer H⁺. (4) Most buffers consist of a weak acid and the salt of that acid, which acts as weak base. (5) Hemoglobin is an important buffer.

(a) 1, 2, 3, and 5 (b) 1, 3, 4, and 5 (c) 1, 3, and 5 (d) 1, 4, and 5 (e) 2, 3, and 5

9. Which of the following hormones regulate fluid loss? (1) antidiuretic hormone, (2) aldosterone, (3) atrial natriuretic peptide, (4) thyroxine, (5) cortisol.

(a) 1, 3, and 5 (b) 1, 2, and 3 (c) 2, 4, and 5 (d) 2, 3, and 4 (e) 1, 3, and 4

10. Which of the following are true concerning ions in the body? (1) They control osmosis of water between fluid compartments. (2) They help maintain acid–base balance. (3) They carry electrical current. (4) They serve as cofactors for enzyme activity. (5) They serve as neurotransmitters under special circumstances.

(a) 1, 3, and 5 (b) 2, 4, and 5 (c) 1, 4, and 5 (d) 1, 2, and 4 (e) 1, 2, 3, and 4

11. Which of the following statements are true? (1) An increase in the carbon dioxide concentration in body fluids increases H⁺ concentration and thus lowers pH. (2) Breathing results in a decline in blood pH. (3) The respiratory buffer mechanism can eliminate a single volatile acid: carbonic acid. (4) The only way to eliminate nonvolatile acids is to excrete H⁺ in the urine. (5) When the diet contains a large amount of protein, normal metabolism produces more acids than bases.

(a) 1, 2, 3, 4, and 5 (b) 1, 3, 4, and 5 (c) 1, 2, 3, and 4 (d) 1, 2, 4, and 5 (e) 1, 3, and 4

12. Concerning acid–base imbalances: (1) Acidosis can cause depression of the central nervous system through depression of synaptic transmission. (2) Renal compensation can resolve respiratory alkalosis or acidosis. (3) A major physiological effect of alkalosis is lack of excitability in the central nervous system and peripheral nerves. (4) Resolution of metabolic acidosis and alkalosis occurs through renal compensation. (5) In adjusting blood pH, renal compensation occurs quickly, but respiratory compensation takes days.

(a) 1, 2, and 5 (b) 1 and 2 (c) 2, 3, and 4 (d) 2, 3, and 5 (e) 1, 2, 3, and 5

13. Which of the following are mismatched? (a) hyperventilation: respiratory acidosis (b) severe diarrhea: metabolic acidosis (c) excessive vomiting: metabolic alkalosis (d) airway obstruction: respiratory alkalosis (e) inability of kidneys to excrete H⁺ from dietary protein metabolism: metabolic acidosis

14. Match the following:

_____ (a) the most abundant cation in intracellular fluid; plays a key role in establishing the resting membrane potential and the sodium/potassium ATPase metabolism

_____ (b) the most abundant mineral in the body; plays an important role in blood clotting, neurotransmitter release, maintenance of muscle tone, and excitability of nervous and muscle tissue

_____ (c) second most common intracellular cation; is a cofactor for enzymes involved in carbohydrate, protein, and Na⁺/K⁺ ATPase metabolism

_____ (d) the most abundant extracellular cation; essential in fluid and electrolyte balance

_____ (e) ions that are mostly combined with lipids, proteins, carbohydrates, nucleic acids, and ATP inside cells

_____ (f) most prevalent extracellular anion; can help balance the level of anions in different fluid compartments

_____ (g) second most prevalent extracellular anion; mainly regulated by the kidneys; important for acid–base balance

_____ (h) substances that act to prevent rapid, drastic changes in the pH of a body fluid

_____ (i) inorganic substances that dissociate into ions when in solution
15. Match the following:
   (a) an abnormal increase in the volume of interstitial fluid
   (b) can occur during renal failure or destruction of body cells, which releases phosphates into the blood
   (c) the swelling of cells due to water moving from plasma into interstitial fluid and then into cells
   (d) occurs when water loss is greater than water gain
   (e) can be caused by excessive sodium in diet or with dehydration
   (f) condition that can occur as water moves out of plasma into interstitial fluid and blood volume decreases
   (g) can be caused by decreased potassium intake or kidney disease; results in muscle fatigue, increased urine output, changes in electrocardiogram
   (h) can occur from hypoparathyroidism
   (i) can be caused by emphysema, pulmonary edema, injury to the respiratory center of the medulla oblongata, airway destruction, or disorders of the muscles involved in breathing
   (j) can be caused by excessive water intake, excessive vomiting, or aldosterone deficiency
   (k) can be caused by actual loss of bicarbonate ions, ketosis, or failure of kidneys to excrete H⁺
   (l) can be caused by excessive vomiting of gastric contents, gastric suctioning, use of certain diuretics, severe dehydration, or excessive intake of alkaline drugs
   (m) can be caused by oxygen deficiency at high altitude, stroke, or severe anxiety

CRITICAL THINKING QUESTIONS

1. Robin is in the early stages of pregnancy and has been vomiting excessively for several days. She became weak, was confused, and was taken to the emergency room. What do you suspect has happened to Robin’s acid–base balance? How would her body attempt to compensate? What electrolytes would be affected by her vomiting, and how do her symptoms reflect those imbalances?

2. Henry is in the intensive care unit because he suffered a severe myocardial infarction three days ago. The lab reports the following values from an arterial blood sample: pH 7.30, HCO₃⁻ = 20 mEq/liter, P₃CO₂ = 32 mmHg. Diagnose Henry’s acid–base status and decide whether compensation is occurring.

3. This summer, Sam is training for a marathon by running 10 miles a day. Describe changes in his fluid balance as he trains.

ANSWERS TO FIGURE QUESTIONS

27.1 Plasma volume equals body mass × percent of body mass that is body fluid × proportion of body fluid that is ECF × proportion of ECF that is plasma × a conversion factor (1 liter/kg).

For males: blood plasma volume = 60 kg × 0.60 × 1/3 × 0.20 × 1 liter/kg = 2.4 liters. Using similar calculations, female blood plasma volume is 2.2 liters.

27.2 Hyperventilation, vomiting, fever, and diuretics all increase fluid loss.

27.3 Negative feedback is in operation because the result (an increase in fluid intake) is opposite to the initiating stimulus (dehydration).

27.4 An elevated aldosterone level promotes abnormally high renal reabsorption of NaCl and water, which expands blood volume and increases blood pressure. Because of the increased blood pressure, more fluid filters out of capillaries and accumulates in the interstitial fluid, causing edema.

27.5 If a solution used for oral rehydration therapy contains a small amount of salt, both the salt and water are absorbed in the gastrointestinal tract, blood volume increases without a decrease in osmolarity, and water intoxication does not occur.

27.6 In ECF, the major cation is Na⁺, and the major anions are Cl⁻ and HCO₃⁻. In ICF, the major cation is K⁺, and the major anions are proteins and organic phosphates (for example, ATP).

27.7 Holding your breath causes blood pH to decrease slightly as CO₂ and H⁺ accumulate in the blood.

27.8 A carbonic anhydrase inhibitor reduces secretion of H⁺ into the urine and reduces reabsorption of Na⁺ and HCO₃⁻ into the blood. It has a diuretic effect and can cause acidosis (lowered pH of the blood) due to loss of HCO₃⁻ in the urine.
The male and female reproductive organs work together to produce offspring. In addition, the female reproductive organs contribute to sustaining the growth of embryos and fetuses.

Sexual reproduction is the process by which organisms produce offspring by making germ cells called gametes (GAM-ëts = spouses). After the male gamete (sperm cell) unites with the female gamete (secondary oocyte)—an event called fertilization—the resulting cell contains one set of chromosomes from each parent. Males and females have anatomically distinct reproductive organs that are adapted for producing gametes, facilitating fertilization, and, in females, sustaining the growth of the embryo and fetus.

The male and female reproductive organs can be grouped by function. The gonads—testes in males and ovaries in females—produce gametes and secrete sex hormones. Various ducts then store and transport the gametes, and accessory sex glands produce substances that protect the gametes and facilitate their movement. Finally, supporting structures, such as the penis in males and the uterus in females, assist the delivery of gametes, and the uterus is also the site for the growth of the embryo and fetus during pregnancy.

Gynecology (gī-ne-KOL-ō-jē; gyneco- = woman; -logy = study of) is the specialized branch of medicine concerned with the diagnosis and treatment of diseases of the female reproductive system. As noted in Chapter 26, urology (ū-ROL-ō-jē) is the study of the urinary system. Urologists also diagnose and treat diseases and disorders of the male reproductive system. The branch of medicine that deals with male disorders, especially infertility and sexual dysfunction, is called andrology (an-DROL-ō-jē; andro- = masculine).
MALE REPRODUCTIVE SYSTEM

OBJECTIVES

- Describe the location, structure, and functions of the organs of the male reproductive system.
- Discuss the process of spermatogenesis in the testes.

The organs of the male reproductive system include the testes, a system of ducts (including the epididymis, ductus deferens, ejaculatory ducts, and urethra), accessory sex glands (seminal vesicles, prostate, and bulbourethral glands), and several supporting structures, including the scrotum and the penis (Figure 28.1). The testes (male gonads) produce sperm and secrete hormones. The duct system transports and stores sperm, assists in their maturation, and conveys them to the exterior. Semen contains sperm plus the secretions provided by the accessory sex glands. The supporting structures have various functions. The penis delivers sperm into the female reproductive tract and the scrotum supports the testes.

Scrotum

The scrotum (SKRÔ-tum = bag), the supporting structure for the testes, consists of loose skin and underlying subcutaneous layer that hangs from the root (attached portion) of the penis (Figure 28.1a). Externally, the scrotum looks like a single pouch of skin separated into lateral portions by a median ridge called the raphe (RA´-fē = seam). Internally, the scrotal septum divides the scrotum into two sacs, each containing a single testis (Figure 28.2 on page 1084). The septum is made up of a subcutaneous layer and muscle tissue called the dartos muscle (DAR-tōs = skinned), which is composed of bundles of smooth muscle fibers.

Figure 28.1 Male organs of reproduction and surrounding structures.

Reproductive organs are adapted for producing new individuals and passing on genetic material from one generation to the next.
The dartos muscle is also found in the subcutaneous layer of the scrotum. Associated with each testis in the scrotum is the cremaster muscle (krē-MAS-ter = suspender), a series of small bands of skeletal muscle that descend as an extension of the internal oblique muscle through the spermatic cord to surround the testes.

The location of the scrotum and the contraction of its muscle fibers regulate the temperature of the testes. Normal sperm production requires a temperature about 2–3°C below core body temperature. This lowered temperature is maintained within the scrotum because it is outside the pelvic cavity. In response to cold temperatures, the cremaster and dartos muscles contract. Contraction of the cremaster muscles moves the testes closer to the body, where they can absorb body heat. Contraction of the dartos muscle causes the scrotum to become tight (wrinkled in appearance), which reduces heat loss. Exposure to warmth reverses these actions.

### Testes

The testes (TES-tēz), or testicles, are paired oval glands in the scrotum measuring about 5 cm (2 in.) long and 2.5 cm (1 in.) in diameter (Figure 28.3 on page 1085). Each testis (singular) has a mass of 10–15 grams. The testes develop near the kidneys, in the posterior portion of the abdomen, and they usually begin their descent into the scrotum through the inguinal canals (passageways in the anterior abdominal wall; see Figure 28.2) during the latter half of the seventh month of fetal development.

A serous membrane called the tunica vaginalis (tunica = sheath), which is derived from the peritoneum and forms during the descent of the testes, partially covers the testes. A collection of serous fluid in the tunica vaginalis is called a hydrocele (HÍ-drō-seł; hydro- = water; -kele = hernia). It may be caused by injury to the testes or inflammation of the epididymis. Usually, no
treatment is required. Internal to the tunica vaginalis is a white fibrous capsule composed of dense irregular connective tissue, the tunica albuginea (al′-bu-JIN-ē-a; albu- = white); it extends inward, forming septa that divide the testes into a series of internal compartments called lobules. Each of the 200–300 lobules contains one to three tightly coiled tubules, the seminiferous tubules (semin- = seed; fer- = to carry), where sperm are produced. The process by which the seminiferous tubules of the testes produce sperm is called spermatogenesis (sper′-ma-tō-JEN-e-sis; genesis = beginning process or production).

The seminiferous tubules contain two types of cells: spermatogenic cells, the sperm-forming cells, and Sertoli cells, which have several functions in supporting spermatogenesis (Figure 28.4 on page 1086). Stem cells called spermatogonia (sper′-ma-tō-GO-nē-ə; -gōnia = offspring; singular is spermatogonium) develop from primordial germ cells (primordi- = primitive or early form) that arise from the yolk sac and enter the testes during the fifth week of development. In the embryonic testes, the primordial germ cells differentiate into spermatogonia, which remain dormant during childhood and actively begin producing sperm at puberty. Toward the lumen of the seminiferous tubule are layers of progressively more mature cells. In order of advancing maturity, these are primary spermatocytes, secondary spermatocytes, spermatids, and sperm cells. After a sperm cell, or spermatozoon (sper′-ma-tō-ZÖ-on; -zoon = life) has formed, it is released into the lumen of the seminiferous tubule. (The plural terms are sperm and spermatozoa.)

Embedded among the spermatogenic cells in the seminiferous tubules are large Sertoli cells or sustentacular cells (sus′-ten-TAK-ū-lar), which extend from the basement membrane to the lumen of the tubule. Internal to the basement membrane and spermatogonia, tight junctions join neighboring Sertoli cells to one another. These junctions form an obstruction known as the blood–testis barrier because substances must first pass through the Sertoli cells before they can reach the developing sperm. By isolating the developing gametes from the blood, the blood–testis barrier prevents an immune response against the spermatogenic cell’s surface antigens, which are recognized as “foreign” by the immune system. The blood–testis barrier does not include spermatogonia.
Figure 28.3 Internal and external anatomy of a testis.

The testses are the male gonads, which produce haploid sperm.

¿What tissue layers cover and protect the testes?
Figure 28.4 Microscopic anatomy of the seminiferous tubules and stages of sperm production (spermatogenesis). Arrows in (b) indicate the progression of spermatogenic cells from least mature to most mature. The \((n)\) and \((2n)\) refer to haploid and diploid numbers of chromosomes, respectively.

Spermatogenesis occurs in the seminiferous tubules of the testes.

Which cells secrete testosterone?

Sertoli cells support and protect developing spermatogenic cells in several ways. They nourish spermatocytes, spermatids, and sperm; phagocytize excess spermatid cytoplasm as development proceeds; and control movements of spermatogenic cells and the release of sperm into the lumen of the seminiferous tubule. They also produce fluid for sperm transport, secrete the hormone inhibin, and regulate the effects of testosterone and FSH (follicle-stimulating hormone).
In the spaces between adjacent seminiferous tubules are clusters of cells called Leydig (interstitial) cells (Figure 28.4). These cells secrete testosterone, the most prevalent androgen. An androgen is a hormone that promotes the development of masculine characteristics. Testosterone also promotes a man’s libido (sexual drive).

**CLINICAL CONNECTION Cryptorchidism**

The condition in which the testes do not descend into the scrotum is called cryptorchidism (krip-TOR-ki-dizm; crypt = hidden; orchid = testis); it occurs in about 3% of full-term infants and about 30% of premature infants. Untreated bilateral cryptorchidism results in sterility because the cells involved in the initial stages of spermatogenesis are destroyed by the higher temperature of the pelvic cavity. The chance of testicular cancer is 30–50 times greater in cryptorchid testes. The testes of about 80% of boys with cryptorchidism will descend spontaneously during the first year of life. The testes remain undescended, the condition can be corrected surgically, ideally before 18 months of age.

### Spermatogenesis

Before you read this section, please review the topic of reproductive cell division in Chapter 3 on pages 97–99. Pay particular attention to Figures 3.33 and 3.34, which appear on pages 98 and 99, respectively.

In humans, spermatogenesis takes 65–75 days. It begins with the spermatogonia, which contain the diploid (2n) number of chromosomes (Figure 28.5). Spermatogonia are types of stem cells: when they undergo mitosis, some spermatogonia remain near the basement membrane of the seminiferous tubule in an undifferentiated state to serve as a reservoir of cells for future cell division and subsequent sperm production. The rest of the spermatogonia lose contact with the basement membrane, squeeze through the tight junctions of the blood-testis barrier, undergo developmental changes, and differentiate into primary spermatocytes (SPER-ma-tó-sitz'). Primary spermatocytes, like spermatogonia, are diploid (2n); that is, they have 46 chromosomes.

Shortly after it forms, each primary spermatocyte replicates its DNA and then meiosis begins (Figure 28.5). In meiosis I, homologous pairs of chromosomes line up at the metaphase plate, and crossing-over occurs. Then, the meiotic spindle pulls one (duplicated) chromosome of each pair to an opposite pole of the dividing cell. The two cells formed by meiosis I are called secondary spermatocytes. Each secondary spermatocyte has 23 chromosomes, the haploid number (n). Each chromosome within a secondary spermatocyte, however, is made up of two chromatids (two copies of the DNA) still attached by a centromere. No replication of DNA occurs in the secondary spermatocytes.

In meiosis II, the chromosomes line up in single file along the metaphase plate, and the two chromatids of each chromosome separate. The four haploid cells resulting from meiosis II are called spermatids. A single primary spermatocyte therefore produces four spermatids via two rounds of cell division (meiosis I and meiosis II).

A unique process occurs during spermatogenesis. As spermatogenic cells proliferate, they fail to complete cytoplasmic separation (cytokinesis). The cells remain in contact via cytoplasmic bridges through their entire development (see Figures 28.4b and 28.5). This pattern of development most likely accounts for the synchronized production of sperm in any given area of seminiferous tubule. It may also have survival value in that half of the sperm contain an X chromosome and half contain a Y chromosome. The larger X chromosome may carry genes needed for spermatogenesis that are lacking on the smaller Y chromosome.

The final stage of spermatogenesis, spermiogenesis (sper’-mi-e-JEN-e-sis), is the development of haploid spermatids into sperm. No cell division occurs in spermiogenesis; each spermatid becomes a single sperm cell. During this process, spermatids transform into elongated, slender sperm. An acrosome (described shortly) forms atop the nucleus, which condenses and elongates, a flagellum develops, and mitochondria multiply. Sertoli cells dispose of the excess cytoplasm that sloughs off. Finally, sperm are released from their connections to the basement membrane of the seminiferous tubule.

**Figure 28.5 Events in spermatogenesis.** Diploid cells (2n) have 46 chromosomes; haploid cells (n) have 23 chromosomes.

![Diagram of spermatogenesis](image)

**What is “reduced” during meiosis I?**
Sertoli cells, an event known as spermiation. Sperm then enter the lumen of the seminiferous tubule. Fluid secreted by Sertoli cells pushes sperm along their way, toward the ducts of the testes. At this point, sperm are not yet able to swim.

**Sperm**

Each day about 300 million sperm complete the process of spermatogenesis. A sperm is about 60 μm long and contains several structures that are highly adapted for reaching and penetrating a secondary oocyte (Figure 28.6). The major parts of a sperm are the head and the tail. The flattened, pointed head of the sperm is about 4–5 μm long. It contains a nucleus with 23 highly condensed chromosomes. Covering the anterior two-thirds of the nucleus is the acrosome (acro- = atop; -some = body), a cap-like vesicle filled with enzymes that help a sperm to penetrate a secondary oocyte to bring about fertilization. Among the enzymes are hyaluronidase and proteases. The tail of a sperm is subdivided into four parts: neck, middle piece, principal piece, and end piece. The neck is the constricted region just behind the head that contains centrioles. The centrioles form the microtubules that comprise the remainder of the tail. The middle piece contains mitochondria arranged in a spiral, which provide the energy (ATP) for locomotion of sperm to the site of fertilization and for sperm metabolism. The principal piece is the longest portion of the tail, and the end piece is the terminal, tapering portion of the tail. Once ejaculated, most sperm do not survive more than 48 hours within the female reproductive tract.

**Hormonal Control of the Testes**

Although the initiating factors are unknown, at puberty certain hypothalamic neurosecretory cells increase their secretion of gonadotropin-releasing hormone (GnRH). This hormone in turn stimulates gonadotrophs in the anterior pituitary to increase their secretion of the two gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Figure 28.7 shows the hormones and negative feedback loops that control secretion of testosterone and spermatogenesis.

LH stimulates Leydig cells, which are located between seminiferous tubules, to secrete the hormone testosterone (tes-TO-s-te-ron). This steroid hormone is synthesized from cholesterol in the testes and is the principal androgen. It is lipid-soluble and readily diffuses out of Leydig cells into the interstitial fluid and then into blood. Via negative feedback, testosterone suppresses secretion of LH by anterior pituitary gonadotrophs and suppresses secretion of GnRH by hypothalamic neurosecretory cells. In some target cells, such as those in the external genitals and prostate, the enzyme 5 alpha-reductase converts testosterone to another androgen called dihydrotestosterone (DHT).

FSH acts indirectly to stimulate spermatogenesis (Figure 28.7). FSH and testosterone act synergistically on the Sertoli cells to stimulate secretion of androgen-binding protein (ABP) into the lumen of the seminiferous tubules and into the interstitial fluid around the spermatogenic cells. ABP binds to testosterone, keeping its concentration high. Testosterone stimulates the final steps of spermatogenesis in the seminiferous tubules. Once the degree of spermatogenesis required for male reproductive functions has been achieved, Sertoli cells release inhibin, a protein hormone named for its role in inhibiting FSH secretion by the anterior pituitary (Figure 28.7). If spermatogenesis is proceeding too slowly, less inhibin is released, which permits more FSH secretion and an increased rate of spermatogenesis.

Testosterone and dihydrotestosterone both bind to the same androgen receptors, which are found within the nuclei of target cells. The hormone–receptor complex regulates gene expression, turning some genes on and others off. Because of these changes, the androgens produce several effects:

- **Prenatal development.** Before birth, testosterone stimulates the male pattern of development of reproductive system ducts and the descent of the testes. Dihydrotestosterone stimulates development of the external genitals (described on page 1121). Testosterone also is converted in the brain to estrogens (feminizing hormones), which may play a role in the development of certain regions of the brain in males.

- **Development of male sexual characteristics.** At puberty, testosterone and dihydrotestosterone bring about development and enlargement of the male sex organs and the development of masculine secondary sexual characteristics. Secondary sex characteristics are traits that distinguish males and females but do not have a direct role in reproduction. These include musculoskeletal growth that results in wide shoulders and narrow hips; facial and chest hair (within hereditary limits) and more hair on other parts of the body; thickening of the skin; increased sebaceous (oil) gland

**Figure 28.6 Parts of a sperm cell.**

About 300 million sperm mature each day.
secretion; and enlargement of the larynx and consequent deepening of the voice.

- Development of sexual function. Androgens contribute to male sexual behavior and spermatogenesis and to sex drive (libido) in both males and females. Recall that the adrenal cortex is the main source of androgens in females.

- Stimulation of anabolism. Androgens are anabolic hor-

**Figure 28.7** Hormonal control of spermatogenesis and actions of testosterone and dihydrotestosterone (DHT). In response to stimulation by FSH and testosterone, Sertoli cells secrete androgen-binding protein (ABP). Dashed red lines indicate negative feedback inhibition.

Release of FSH is stimulated by GnRH and inhibited by inhibin; release of LH is stimulated by GnRH and inhibited by testosterone.

**Figure 28.8** Negative feedback control of blood level of testosterone.

- Androgen receptor

Which hormones inhibit secretion of FSH and LH by the anterior pituitary?
blood that flows from the hypothalamus to the anterior pituitary. Gonadotrophs in the anterior pituitary then release less LH, so the concentration of LH in systemic blood falls. With less stimulation by LH, the Leydig cells in the testes secrete less testosterone, and there is a return to homeostasis. If the testosterone concentration in the blood falls too low, however, GnRH is again released by the hypothalamus and stimulates secretion of LH by the anterior pituitary. LH in turn stimulates testosterone production by the testes.

**CHECKPOINT**
1. Describe the function of the scrotum in protecting the testes from temperature fluctuations.
2. Describe the internal structure of a testis. Where are sperm cells produced? What are the functions of Sertoli cells and Leydig cells?
3. Describe the principal events of spermatogenesis.
4. Identify the parts of a sperm cell, and list the functions of each.
5. What are the roles of FSH, LH, testosterone, and inhibin in the male reproductive system? How is secretion of these hormones controlled?

**Reproductive System Ducts in Males**

**Ducts of the Testis**
Pressure generated by the fluid secreted by Sertoli cells pushes sperm and fluid along the lumen of seminiferous tubules and then into a series of very short ducts called straight tubules (see Figure 28.2). The straight tubules lead to a network of ducts in the testis called the rete testis (RE-tē = network). From the rete testis, sperm move into a series of coiled efferent ducts in the epididymis that empty into a single tube called the ductus epididymis.

**Epididymis**
The epididymis (ep’-i-DID-i-mis; epi- = above or over; -didymis = testis) is a comma-shaped organ about 4 cm (1.5 in.) long that lies along the posterior border of each testis (see Figure 28.3a). The plural is epididymides (ep’-i-did-IM-ī-dēz). Each epididymis consists mostly of the tightly coiled ductus epididymis. The efferent ducts from the testis join the ductus epididymis at the larger, superior portion of the epididymis called the head. The body is the narrow midportion of the epididymis, and the tail is the smaller, inferior portion. At its distal end, the tail of the epididymis continues as the ductus (vas) deferens (discussed shortly).

The ductus epididymis would measure about 6 m (20 ft) in length if it were uncoiled. It is lined with pseudostratified columnar epithelium and encircled by layers of smooth muscle. The free surfaces of the columnar cells contain stereocilia, which despite their name are long, branching microvilli (not cilia) that increase the surface area for the reabsorption of degenerated sperm. Connective tissue around the muscle layer attaches the loops of the ductus epididymis and carries blood vessels and nerves.

Functionally, the epididymis is the site of sperm maturation, the process by which sperm acquire motility and the ability to fertilize an ovum. This occurs over a period of about 14 days. The epididymis also helps propel sperm into the ductus (vas) deferens during sexual arousal by peristaltic contraction of its smooth muscle. In addition, the epididymis stores sperm, which remain viable here for up to several months. Any stored sperm that are not ejaculated by that time are eventually reabsorbed.

**Ductus Deferens**
Within the tail of the epididymis, the ductus epididymis becomes less convoluted, and its diameter increases. Beyond this point, the duct is known as the ductus deferens or vas deferens (see Figure 28.3a). The ductus deferens, which is about 45 cm (18 in.) long, ascends along the posterior border of the epididymis through the spermatic cord and then enters the pelvic cavity. There it loops over the ureter and passes over the side and down the posterior surface of the urinary bladder (see Figure 28.1a). The dilated terminal portion of the ductus deferens is the ampulla (am-PUL-la = little jar; Figure 28.9). The mucosa of the ductus deferens consists of pseudostratified columnar epithelium and lamina propria (areolar connective tissue). The muscularis is composed of three layers of smooth muscle; the inner and outer layers are longitudinal, and the middle layer is circular.

Functionally, the ductus deferens conveys sperm during sexual arousal from the epididymis toward the urethra by peristaltic contractions of its muscular coat. Like the epididymis, the ductus deferens also can store sperm for several months. Any stored sperm that are not ejaculated by that time are eventually reabsorbed.

**Spermatic Cord**
The spermatic cord is a supporting structure of the male reproductive system that ascends out of the scrotum (see Figure 28.2). It consists of the ductus (vas) deferens as it ascends through the scrotum, the testicular artery, veins that drain the testes and carry testosterone into circulation (the pampiniform plexus), autonomic nerves, lymphatic vessels, and the cremaster muscle. The term varicocele (VAR-i-kō-sel; varico- = varicose; -kele = hernia) refers to a swelling in the scrotum due to a dilation of the veins that drain the testes. It is usually more apparent when the person is standing and typically does not require treatment. The spermatic cord and ilioinguinal nerve pass through the inguinal canal (IN-gwin-al = groin), an oblique passageway in the anterior abdominal wall just superior and parallel to the medial half of the inguinal ligament. The canal, which is about 4–5 cm (about 2 in.) long, originates at the deep (abdominal) inguinal ring, a slitlike opening in the aponeurosis of the transversus abdominis muscle; the canal ends at the superficial (subcutaneous) inguinal ring (see Figure 28.2), a somewhat triangular opening in the aponeurosis of the external oblique muscle. In females, the round ligament of the uterus and ilioinguinal nerve pass through the inguinal canal.
Figure 28.9 Locations of several accessory reproductive organs in males. The prostate, urethra, and penis have been sectioned to show internal details.

The male urethra has three subdivisions: the prostatic, membranous, and spongy (penile) urethra.

### Functions of Accessory Sex Gland Secretions

1. The seminal vesicles secrete alkaline, viscous fluid that helps neutralize acid in the female reproductive tract, provides fructose for ATP production by sperm, contributes to sperm motility and viability, and helps semen coagulate after ejaculation.

2. The prostate secretes a milky, slightly acidic fluid that helps semen coagulate after ejaculation and subsequently breaks down the clot.

3. The bulbourethral (Cowper’s) glands secrete alkaline fluid that neutralizes the acidic environment of the urethra and mucus that lubricates the lining of the urethra and the tip of the penis during sexual intercourse.

---

**CLINICAL CONNECTION** Vasectomy

The principal method for sterilization of males is a **vasectomy** (vas-EK-tō-mē; -ectomy = cut out), in which a portion of each ductus deferens is removed. An incision is made on either side of the scrotum, the ducts are located and cut, each is tied (ligated) in two places with stitches, and the portion between the ties is removed. Although sperm production continues in the testes, sperm can no longer reach the exterior. The sperm degenerate and are destroyed by phagocytosis. Because the blood vessels are not cut, testosterone levels in the blood remain normal, so vasectomy has no effect on sexual desire, performance, and ejaculation. If done correctly, it is close to 100% effective. The procedure can be reversed, but the chance of regaining fertility is only 30–40%.

---

**FIGURE 28.9 CONTINUES**
Ejaculatory Ducts

Each ejaculatory duct (e-JAK-ū-la-tō'-rē; ejacul- = to expel) is about 2 cm (1 in.) long and is formed by the union of the duct from the seminal vesicle and the ampulla of the ductus (vas) deferens (Figure 28.9). The ejaculatory ducts form just superior to the base (superior portion) of the prostate and pass inferiorly and anteriorly through the prostate. They terminate in the prostatic urethra, where they eject sperm and seminal vesicle secretions just before the release of semen from the urethra to the exterior.

Urethra

In males, the urethra is the shared terminal duct of the reproductive and urinary systems; it serves as a passageway for both semen and urine. About 20 cm (8 in.) long, it passes through the prostate, the deep muscles of the perineum, and the penis, and is subdivided into three parts (see Figures 28.1 and 26.22). The prostatic urethra is 2–3 cm (1 in.) long and passes through the prostate. As this duct continues inferiorly, it passes through the deep muscles of the perineum, where it is known as the membranous urethra. The membranous urethra is about 1 cm (0.5 in.) in length. As this duct passes through the corpus spongiosum of the penis, it is known as the spongy (penile) urethra, which is about 15–20 cm (6–8 in.) long. The spongy urethra ends at the external urethral orifice. The histology of the male urethra may be reviewed on page 1052 of Chapter 26.

**CHECKPOINT**

6. Which ducts transport sperm within the testes?
7. Describe the location, structure, and functions of the ductus epididymis, ductus (vas) deferens, and ejaculatory duct.
8. Give the locations of the three subdivisions of the male urethra.
9. Trace the course of sperm through the system of ducts from the seminiferous tubules to the urethra.
10. List the structures within the spermatic cord.

What accessory sex gland contributes the majority of the seminal fluid?
Accessory Sex Glands

The ducts of the male reproductive system store and transport sperm cells, but the accessory sex glands secrete most of the liquid portion of semen. The accessory sex glands include the seminal vesicles, the prostate, and the bulbourethral glands.

Seminal Vesicles

The paired seminal vesicles (VES-i-kuls) or seminal glands are convoluted pouchlike structures, about 5 cm (2 in.) in length, lying posterior to the base of the urinary bladder and anterior to the rectum (Figure 28.9). Through the seminal vesicle ducts they secrete an alkaline, viscous fluid that contains fructose (a mono-saccharide sugar), prostaglandins, and clotting proteins that are different from those in blood. The alkaline nature of the seminal fluid helps to neutralize the acidic environment of the male urethra and female reproductive tract that otherwise would inactivate and kill sperm. The fructose is used for ATP production by sperm. Prostaglandins contribute to sperm motility and viability and may stimulate smooth muscle contractions within the female reproductive tract. The clotting proteins help semen coagulate after ejaculation. Fluid secreted by the seminal vesicles normally constitutes about 60% of the volume of semen.

Prostate

The prostate (PROS-tāt) is a single, doughnut-shaped gland about the size of a golf ball. It measures about 4 cm (1.6 in.) from side to side, about 3 cm (1.2 in.) from top to bottom, and about 2 cm (0.8 in.) from front to back. It is inferior to the urinary bladder and surrounds the prostatic urethra (Figure 28.9). The prostate slowly increases in size from birth to puberty. It then expands rapidly until about age 30, after which time its size typically remains stable until about age 45, when further enlargement may occur.

The prostate secretes a milky, slightly acidic fluid (pH about 6.5) that contains several substances. (1) Citric acid in prostatic fluid is used by sperm for ATP production via the Krebs cycle. (2) Several proteolytic enzymes, such as prostate-specific antigen (PSA), pepsinogen, lysozyme, amylase, and hyaluronidase, eventually break down the clotting proteins from the seminal vesicles. (3) The function of the acid phosphatase secreted by the prostate is unknown. (4) Seminalplasmin in prostatic fluid is an antibiotic that can destroy bacteria. Seminalplasmin may help decrease the number of naturally occurring bacteria in semen and in the lower female reproductive tract. Secretions of the prostate enter the prostatic urethra through many prostatic ducts. Prostatic secretions make up about 25% of the volume of semen and contribute to sperm motility and viability.

Bulbourethral Glands

The paired bulbourethral glands (bul’-bō-ū-RĒ-thral), or Cowper’s glands, are about the size of peas. They are located inferior to the prostate on either side of the membranous urethra within the deep muscles of the perineum, and their ducts open into the spongy urethra (Figure 28.9). During sexual arousal, the bulbourethral glands secrete an alkaline fluid into the urethra that protects the passing sperm by neutralizing acids from urine in the urethra. They also secrete mucus that lubricates the end of the penis and the lining of the urethra, decreasing the number of sperm damaged during ejaculation.

Semen

Semen (= seed) is a mixture of sperm and seminal fluid, a liquid that consists of the secretions of the seminiferous tubules, seminal vesicles, prostate, and bulbourethral glands. The volume of semen in a typical ejaculation is 2.5–5 milliliter (mL), with 50–150 million sperm per mL. When the number falls below 20 million/mL, the male is likely to be infertile. A very large number of sperm is required for successful fertilization because only a tiny fraction ever reaches the secondary oocyte.

Despite the slight acidity of prostatic fluid, semen has a slightly alkaline pH of 7.2–7.7 due to the higher pH and larger volume of fluid from the seminal vesicles. The prostatic secretion gives semen a milky appearance, and fluids from the seminal vesicles and bulbourethral glands give it a sticky consistency. Seminal fluid provides sperm with a transportation medium, nutrients, and protection from the hostile acidic environment of the male’s urethra and the female’s vagina.

Once ejaculated, liquid semen coagulates within 5 minutes due to the presence of clotting proteins from the seminal vesicles. The functional role of semen coagulation is not known, but the proteins involved are different from those that cause blood coagulation. After about 10 to 20 minutes, semen liquefies because prostate-specific antigen (PSA) and other proteolytic enzymes produced by the prostate break down the clot. Abnormal or delayed liquefaction of clotted semen may cause complete or partial immobilization of sperm, thereby inhibiting their movement through the cervix of the uterus. The presence of blood in semen is called hemospermia (hē-mō-SPER-me-a; hemo- = blood; sperma = seed). In most cases, it is caused by inflammation of the blood vessels lining the seminal vesicles; it is usually treated with antibiotics.

Penis

The penis contains the urethra and is a passageway for the ejaculation of semen and the excretion of urine (Figure 28.10). It is cylindrical in shape and consists of a body, glans penis, and a root. The body of the penis is composed of three cylindrical masses of tissue, each surrounded by fibrous tissue called the tunica albuginea (Figure 28.10). The two dorsolateral masses are called the corpora cavernosa penis (corpora = main bodies; cavernosa = hollow). The smaller midventral mass, the corpus spongiosum penis, contains the spongy urethra and keeps it open during ejaculation. Skin and a subcutaneous layer enclose all three masses, which consist of erectile tissue. Erectile tissue is composed of numerous blood sinuses (vascular spaces) lined by endothelial cells and surrounded by smooth muscle and elastic connective tissue.
Which tissue masses form the erectile tissue in the penis, and why do they become rigid during sexual arousal?
FEMALE REPRODUCTIVE SYSTEM

**OBJECTIVES**

- Describe the location, structure, and functions of the organs of the female reproductive system.
- Discuss the process of oogenesis in the ovaries.

The organs of the **female reproductive system** (Figure 28.11) include the ovaries (female gonads); the uterus (fallopian) tubes, or oviducts; the uterus; the vagina; and external organs,
cannot attain them. Other causes include a spinal cord disorder, leukemia, sickle-cell disease, or a pelvic tumor.

**Ejaculation** (ē-jak-ă-lā-shun; *ejactus* = to throw out), the powerful release of semen from the urethra to the exterior, is a sympathetic reflex coordinated by the lumbar portion of the spinal cord. As part of the reflex, the smooth muscle sphincter at the base of the urinary bladder closes, preventing urine from being expelled during ejaculation, and semen from entering the urinary bladder. Even before ejaculation occurs, peristaltic contractions in the epididymis, ductus (vas) deferens, seminal vesicles, ejaculatory ducts, and prostate propel semen into the penile portion of the urethra (spongy urethra). Typically, this leads to **emission** (ē-MISH-un), the discharge of a small volume of semen before ejaculation. Emission may also occur during sleep (nocturnal emission). The musculature of the penis (bulbospongiosus, ischiocavernosus, and superficial transverse perineus muscles), which is supplied by the pudendal nerve, also contracts at ejaculation (see Figure 11.13 on page 369).

Once sexual stimulation of the penis has ended, the arterioles supplying the erectile tissue of the penis constrict and the smooth muscle within erectile tissue contracts, making the blood sinuses smaller. This relieves pressure on the veins supplying the penis and allows the blood to drain through them. Consequently, the penis returns to its flaccid (relaxed) state.

**CHECKPOINT**

11. Briefly explain the locations and functions of the seminal vesicles, the prostate, and the bulbourethral (Cowper’s) glands.
12. What is semen? What is its function?
13. Explain the physiological processes involved in erection and ejaculation.

---

The distal end of the corpus spongiosum penis is a slightly enlarged, acorn-shaped region called the **glans penis**; its margin is the **corona**. The distal urethra enlarges within the glans penis and forms a terminal slitlike opening, the **external urethral orifice**. Covering the glans in an uncircumcised penis is the loosely fitting **prepuce** (PRE-pooz), or foreskin.

The root of the penis is the attached portion (proximal portion). It consists of the **bulb of the penis**, the expanded portion of the base of the corpus spongiosum penis, and the **crura of the penis** (singular is *crus* = resembling a leg), the two separated and tapered portions of the corpora cavernosa penis. The bulb of the penis is attached to the inferior surface of the deep muscles of the perineum and is enclosed by the bulbospongious muscle, a muscle that aids ejaculation. Each crus of the penis bends laterally away from the bulb of the penis to attach to the ischial and inferior pubic rami and is surrounded by the ischiocavernous muscle (see Figure 11.13 on page 369). The weight of the penis is supported by two ligaments that are continuous with the fascia of the penis. (1) The **fundiform ligament** arises from the inferior part of the linea alba. (2) The **suspensory ligament of the penis** arises from the pubic symphysis.

**CLINICAL CONNECTION**

**Premature Ejaculation**

A premature ejaculation is ejaculation that occurs too early, for example, during foreplay or upon or shortly after penetration. It is usually caused by anxiety, other psychological causes, or an unusually sensitive foreskin or glans penis. For most males, premature ejaculation can be overcome by various techniques (such as squeezing the penis between the glans penis and shaft as ejaculation approaches), behavioral therapy, or medication.

**CLINICAL CONNECTION**

**Circumcision** (= to cut around) is a surgical procedure in which part of or the entire prepuce is removed. It is usually performed just after delivery, 3 to 4 days after birth, or on the eighth day as part of a Jewish religious rite. Although most health-care professionals find no medical justification for circumcision, some feel that it has benefits, such as a lower risk of urinary tract infections, protection against penile cancer, and possibly a lower risk for sexually transmitted diseases. Indeed, studies in several African villages have found lower rates of HIV infection among circumcised men.

Upon sexual stimulation (visual, tactile, auditory, olfactory, or imagined), parasympathetic fibers from the sacral portion of the spinal cord initiate and maintain an **erection**, the enlargement and stiffening of the penis. The parasympathetic fibers release and cause local production of nitric oxide (NO). The NO causes smooth muscle in the walls of arterioles supplying erectile tissue to relax, which allows these blood vessels to dilate. This in turn causes large amounts of blood to enter the erectile tissue of the penis. NO also causes smooth muscle in the walls of arterioles supplying erectile tissue to relax, resulting in widening of the blood sinuses. The combination of increased blood flow and widening of the blood sinuses results in an erection. Expansion of the blood sinuses also compresses the veins that drain the penis; the slowing of blood outflow helps to maintain the erection.

The term **priapism** (PRI-a-pizm) refers to a persistent and usually painful erection of the penis that does not involve sexual desire or excitement. The condition may last up to several hours and is accompanied by pain and tenderness. It results from abnormalities of blood vessels and nerves, usually in response to medication used to produce erections in males who otherwise
Functions of the Female Reproductive System

1. The ovaries produce secondary oocytes and hormones, including progesterone and estrogens (female sex hormones), inhibin, and relaxin.
2. The uterine tubes transport a secondary oocyte to the uterus and normally are the sites where fertilization occurs.
3. The uterus is the site of implantation of a fertilized ovum, development of the fetus during pregnancy, and labor.
4. The vagina receives the penis during sexual intercourse and is a passageway for childbirth.
5. The mammary glands synthesize, secrete, and eject milk for nourishment of the newborn.

Which structures in males are homologous to the ovaries, the clitoris, the paraurethral glands, and the greater vestibular glands?
which are collectively called the vulva, or pudendum. The mammary glands are considered part of both the integumentary system and the female reproductive system.

**Ovaries**

The ovaries (egg receptacles), which are the female gonads, are paired glands that resemble unshelled almonds in size and shape; they are homologous to the testes. (Here *homologous* means that two organs have the same embryonic origin.) The ovaries produce (1) gametes, secondary oocytes that develop into mature ova (eggs) after fertilization, and (2) hormones, including progesterone and estrogens (the female sex hormones), inhibin, and relaxin.

The ovaries, one on either side of the uterus, descend to the brim of the superior portion of the pelvic cavity during the third month of development. A series of ligaments holds them in position (Figure 28.12). The **broad ligament** of the uterus (see also Figure 28.11b), which is itself part of the parietal peritoneum, attaches to the ovaries by a double-layered fold of peritoneum called the **mesovarium**. The **ovarian ligament** anchors the ovaries to the uterus, and the **suspensory ligament** attaches them to the pelvic wall. Each ovary contains a **hilum**, the point of entrance and exit for blood vessels and nerves along which the mesovarium is attached.

**Histology of the Ovary**

Each ovary consists of the following parts (Figure 28.13):

- The **germinal epithelium** (*germen* = sprout or bud) is a layer of simple epithelium (low cuboidal or squamous) that covers the surface of the ovary. We now know that the term germinal epithelium in humans is not accurate because it does not give rise to ova; the name came about because, at one time, people believed that it did. We have since learned that the cells that produce ova arise from the yolk sac and migrate to the ovaries during embryonic development.
- The **tunica albuginea** is a whitish capsule of dense irregular connective tissue located immediately deep to the germinal epithelium.
- The **ovarian cortex** is a region just deep to the tunica albuginea. It consists of ovarian follicles (described shortly) surrounded by dense irregular connective tissue that contains collagen fibers and fibroblast-like cells called *stromal cells*.
- The **ovarian medulla** is deep to the ovarian cortex. The border between the cortex and medulla is indistinct, but the medulla consists of more loosely arranged connective tissue and contains blood vessels, lymphatic vessels, and nerves.

**Figure 28.12** Relative positions of the ovaries, the uterus, and the ligaments that support them.

Ligaments holding the ovaries in position are the mesovarium, the ovarian ligament, and the suspensory ligament.

To which structures do the mesovarium, ovarian ligament, and suspensory ligament anchor the ovary?
Figure 28.13 Histology of the ovary. The arrows in (a) indicate the sequence of developmental stages that occur as part of the maturation of an ovum during the ovarian cycle.

The ovaries are the female gonads; they produce haploid oocytes.

What structures in the ovary contain endocrine tissue, and what hormones do they secrete?
Ovarian follicles (folliculus = little bag) are in the cortex and consist of oocytes in various stages of development, plus the cells surrounding them. When the surrounding cells form a single layer, they are called follicular cells; later in development, when they form several layers, they are referred to as granulosa cells. The surrounding cells nourish the developing oocyte and begin to secrete estrogens as the follicle grows larger.

A mature (graafian) follicle is a large, fluid-filled follicle that is ready to rupture and expel its secondary oocyte, a process known as ovulation.

A corpus luteum (= yellow body) contains the remnants of a mature follicle after ovulation. The corpus luteum produces progesterone, estrogens, relaxin, and inhibin until it degenerates into fibrous scar tissue called the corpus albicans (= white body).

Oogenesis and Follicular Development

The formation of gametes in the ovaries is termed oogenesis (o- o-JEN-e-sis; oo- = egg). In contrast to spermatogenesis, which begins in males at puberty, oogenesis begins in females before they are even born. Oogenesis occurs in essentially the same manner as spermatogenesis; meiosis (see Chapter 3) takes place and the resulting germ cells undergo maturation.

During early fetal development, primordial (primitive) germ cells migrate from the yolk sac to the ovaries. There, germ cells differentiate within the ovaries into oogonia (o-ö-GÖ-nē-ä; singular is oogonium). Oogonia are diploid (2n) stem cells that divide mitotically to produce millions of germ cells. Even before birth, most of these germ cells degenerate in a process known as atresia (a-TRÉ-zē-a). A few, however, develop into larger cells called primary oocytes (Ö-ö-sītē) that enter prophase of meiosis I during fetal development but do not complete that phase until after puberty. During this arrested stage of development, each primary oocyte is surrounded by a single layer of flat follicular cells, and the entire structure is called a primordial follicle (Figure 28.14a). The ovarian cortex surrounding the primordial follicles consists of collagen fibers and fibroblast-like stromal cells. At birth, approximately 200,000 to 2,000,000 primary oocytes remain in each ovary. Of these, about 40,000 are still present at puberty, and around 400 will mature and ovulate during a woman’s reproductive lifetime. The remainder of the primary oocytes undergo atresia.

Each month after puberty until menopause, gonadotropins (FSH and LH) secreted by the anterior pituitary further stimulate the development of several primordial follicles, although only one will typically reach the maturity needed for ovulation. A few primordial follicles start to grow, developing into primary follicles (Figure 28.14b). Each primary follicle consists of a primary oocyte that is surrounded in a later stage of development by several layers of cuboidal and low-columnar cells called granulosa cells. The outermost granulosa cells rest on a basement membrane. As the primary follicle grows, it forms a clear glycoprotein layer called the zona pellucida (pe-LOO-is-da) between the primary oocyte and the granulosa cells. In addition, stromal cells surrounding the basement membrane begin to form an organized layer called the theca folliculi (THÉ-ka fo-LIK-ū-li).

Figure 28.14 Ovarian follicles.

As an ovarian follicle enlarges, follicular fluid accumulates in a cavity called the antrum.
What happens to most ovarian follicles?
With continuing maturation, a primary follicle develops into a secondary follicle (Figure 28.14c). In a secondary follicle, the theca differentiates into two layers: (1) the theca interna, a highly vascularized internal layer of cuboidal secretory cells that secrete estrogens and (2) the theca externa, an outer layer of stromal cells and collagen fibers. In addition, the granulosa cells begin to secrete follicular fluid, which builds up in a cavity called the antrum in the center of the secondary follicle. The innermost layer of granulosa cells becomes firmly attached to the zona pellucida and is now called the corona radiata (corona = crown; radiata = radiation) (Figure 28.14c).

The secondary follicle eventually becomes larger, turning into a mature (graafian) follicle (Figure 28.14d). While in this follicle, and just before ovulation, the diploid primary oocyte completes meiosis I, producing two haploid (n) cells of unequal size—each with 23 chromosomes (Figure 28.15). The smaller cell produced by meiosis I, called the first polar body, is essentially a packet of discarded nuclear material. The larger cell, known as the secondary oocyte, receives most of the cytoplasm. Once a secondary oocyte is formed, it begins meiosis II but then stops in metaphase. The mature (graafian) follicle soon ruptures and releases its secondary oocyte, a process known as ovulation.

At ovulation, the secondary oocyte is expelled into the pelvic cavity together with the first polar body and corona radiata. Normally these cells are swept into the uterine tube. If fertilization does not occur, the cells degenerate. If sperm are present in the uterine tube and one penetrates the secondary oocyte, how-

does the age of a primary oocyte in a female compare with the age of a primary spermatocyte in a male?

CHECKPOINT
14. How are the ovaries held in position in the pelvic cavity?
15. Describe the microscopic structure and functions of an ovary.
16. Describe the principal events of oogenesis.

Table 28.1 on page 1102 summarizes the events of oogenesis and follicular development.

● CLINICAL CONNECTION Ovarian Cysts

An ovarian cyst is a fluid-filled sac in or on an ovary. Such cysts are relatively common, are usually noncancerous, and frequently disappear on their own. Cancerous cysts are more likely to occur in women over 40. Ovarian cysts may cause pain, pressure, a dull ache, or fullness in the abdomen; pain during sexual intercourse; delayed, painful, or irregular menstrual periods; abrupt onset of sharp pain in the lower abdomen; and/or vaginal bleeding. Most ovarian cysts require no treatment, but larger ones (more than 5 cm or 2 in.) may be removed surgically.

Figure 28.15 Oogenesis. Diploid cells (2n) have 46 chromosomes; haploid cells (n) have 23 chromosomes.
Uterine Tubes

Females have two uterine (fallopian) tubes, or oviducts, that extend laterally from the uterus (Figure 28.16). The tubes, which measure about 10 cm (4 in.) long, lie between the folds of the broad ligaments of the uterus. They provide a route for sperm to reach an ovum and transport secondary oocytes and fertilized ova from the ovaries to the uterus. The funnel-shaped portion of each tube, called the infundibulum, is close to the ovary but is open to the pelvic cavity. It ends in a fringe of fingerlike projections called fimbriae (FIM-bré-ā = fringe), one of which is attached to the lateral end of the ovary. From the infundibulum,
the uterine tube extends medially and eventually inferiorly and attaches to the superior lateral angle of the uterus. The **ampulla** of the uterine tube is the widest, longest portion, making up about the lateral two-thirds of its length. The **isthmus** of the uterine tube is the more medial, short, narrow, thick-walled portion that joins the uterus.

Histologically, the uterine tubes are composed of three layers: mucosa, muscularis, and serosa. The mucosa consists of epithelium and lamina propria (areolar connective tissue). The epithelium contains ciliated simple columnar cells, which function as a “ciliary conveyor belt” to help move a fertilized ovum (or secondary oocyte) within the uterine tube toward the uterus, and nonciliated cells called **peg cells**, which have microvilli and secrete a fluid that provides nutrition for the ovum (Figure 28.17). The middle layer, the muscularis, is composed of an inner, thick, circular ring of smooth muscle and an outer, thin region of longitudinal smooth muscle. Peristaltic contractions of the muscularis and the ciliary action of the mucosa help move the oocyte or fertilized ovum toward the uterus. The outer layer of the uterine tubes is a serous membrane, the serosa.

Local currents produced by movements of the fimbriae, which surround the ovary during ovulation, sweep the ovulated secondary oocyte from the pelvic cavity into the uterine tube. A sperm cell usually encounters and fertilizes a secondary oocyte in the ampulla of the uterine tube, although fertilization in the pelvic cavity is not uncommon. Fertilization can occur at any time up to about 24 hours after ovulation. Some hours after fertilization, the nuclear materials of the haploid ovum and sperm material combine to form a cell called the **zygote**.
Figure 28.17 Histology of the uterine (fallopian) tube. (See Tortora, A Photographic Atlas of the Human Body, Second Edition, Figure 14.11a.)

Peristaltic contractions of the muscularis and ciliary action of the mucosa of the uterine tube help move the oocyte or fertilized ovum toward the uterus.

What types of cells line the uterine tubes?

The diploid fertilized ovum is now called a zygote and begins to undergo cell divisions while moving toward the uterus. It arrives at the uterus 6 to 7 days after ovulation.

Uterus

The uterus (womb) serves as part of the pathway for sperm deposited in the vagina to reach the uterine tubes. It is also the site of implantation of a fertilized ovum, development of the fetus during pregnancy, and labor. During reproductive cycles when implantation does not occur, the uterus is the source of menstrual flow.

Anatomy of the Uterus

Situated between the urinary bladder and the rectum, the uterus is the size and shape of an inverted pear (see Figure 28.16). In females who have never been pregnant, it is about 7.5 cm (3 in.) long, 5 cm (2 in.) wide, and 2.5 cm (1 in.) thick. The uterus is larger in females who have recently been pregnant, and smaller (atrophied) when sex hormone levels are low, as occurs after menopause.

Anatomical subdivisions of the uterus include: (1) a dome-shaped portion superior to the uterine tubes called the fundus, (2) a tapering central portion called the body, and (3) an inferior narrow portion called the cervix that opens into the vagina. Between the body of the uterus and the cervix is the isthmus (IS-nus), a constricted region about 1 cm (0.5 in.) long. The interior of the body of the uterus is called the uterine cavity, and the interior of the cervix is called the cervical canal. The cervical canal opens into the uterine cavity at the internal os (os = mouthlike opening) and into the vagina at the external os.

Normally, the body of the uterus projects anteriorly and superiorly over the urinary bladder in a position called anteflexion. The cervix projects inferiorly and posteriorly and enters the anterior wall of the vagina at nearly a right angle (see Figure 28.11). Several ligaments that are either extensions of the peritoneal peritoneum or fibromuscular cords maintain the position of the uterus (see Figure 28.12). The paired broad ligaments are double folds of peritoneum attaching the uterus to either side of the pelvic cavity. The paired uterosacral ligaments, also peritoneal extensions, lie on either side of the rectum and connect the uterus to the sacrum. The cardinal (lateral cervical) ligaments are located inferior to the bases of the broad ligaments and extend from the pelvic wall to the cervix and vagina. The round ligaments are bands of fibrous connective tissue between the layers of the broad ligament; they extend from a point on the uterus just inferior to the uterine tubes to a portion of the labia majora of the external genitalia. Although the ligaments normally maintain the anteflexed position of the uterus, they also allow the uterine body enough movement such that the uterus may become malpositioned. A posterior tilting of the uterus, called retroflexion (retro- = backward or behind), is a harmless variation of the normal position of the uterus. There is often no cause for the condition, but it may occur after childbirth.
Histology of the Uterus

Histologically, the uterus consists of three layers of tissue: perimetrium, myometrium, and endometrium (Figure 28.18). The outer layer—the perimetrium (peri- = around; -metrium = uterus) or serosa—is part of the visceral peritoneum; it is composed of simple squamous epithelium and areolar connective tissue. Laterally, it becomes the broad ligament. Anteriorly, it covers the urinary bladder and forms a shallow pouch, the vesicouterine pouch (ves= bladder; see Figure 28.11). Posteriorly, it covers the rectum and forms a deep pouch between the uterus and urinary bladder, the rectouterine pouch (rek- = rectum; pouch of Douglas—the most inferior point in the pelvic cavity).

What structural features of the endometrium and myometrium contribute to their functions?
The middle layer of the uterus, the myometrium (myo- = muscle), consists of three layers of smooth muscle fibers that are thickest in the fundus and thinnest in the cervix. The thicker middle layer is circular; the inner and outer layers are longitudinal or oblique. During labor and childbirth, coordinated contractions of the myometrium in response to oxytocin from the posterior pituitary help expel the fetus from the uterus.

The inner layer of the uterus, the endometrium (endo- = within), is highly vascularized and has three components: (1) An innermost layer composed of simple columnar epithelium (ciliated and secretory cells) lines the lumen. (2) An underlying endometrial stroma is a very thick region of lamina propria (areolar connective tissue). (3) Endometrial (uterine) glands develop as invaginations of the luminal epithelium and extend almost to the myometrium. The endometrium is divided into two layers. The stratum functionalis (functional layer) lines the uterine cavity and sloughs off during menstruation. The deeper layer, the stratum basalis (basal layer), is permanent and gives rise to a new stratum functionalis after each menstruation.

Branches of the internal iliac artery called uterine arteries (Figure 28.19) supply blood to the uterus. Uterine arteries give off branches called arcuate arteries (= shaped like a bow) that are arranged in a circular fashion in the myometrium. These arteries branch into radial arteries that penetrate deeply into the endometrium. Just before the branches enter the endometrium, they divide into two kinds of arterioles: Straight arterioles supply the stratum basalis with the materials needed to regenerate the stratum functionalis; spiral arterioles supply the stratum functionalis and change markedly during the menstrual cycle. Blood leaving the uterus is drained by the uterine veins into the internal iliac veins. The extensive blood supply of the uterus is essential to support regrowth of a new stratum functionalis after menstruation, implantation of a fertilized ovum, and development of the placenta.

Cervical Mucus

The secretory cells of the mucosa of the cervix produce a secretion called cervical mucus, a mixture of water, glycoproteins, lipids, enzymes, and inorganic salts. During their reproductive years, females secrete 20–60 mL of cervical mucus per day. Cervical mucus is more hospitable to sperm at or near the time of ovulation because it is then less viscous and more alkaline (pH 8.5). At other times, a more viscous mucus forms a cervical plug that physically impedes sperm penetration. Cervical mucus supplements the energy needs of sperm, and both the cervix and cervical mucus protect sperm from phagocytes and the hostile environment of the vagina and uterus. Cervical mucus may also play a role in capacitation—a series of functional changes that
The vagina contains large stores of glycogen, the decomposition female during intercourse with an infected male. The mucosa of viruses—for example, HIV (the virus that causes AIDS)—to a series of transverse folds called rugae. Dendritic cells in the mucosa are antigen-presenting cells (described on page 850). Unfortunately, they also participate in the transmission of viruses—for example, HIV (the virus that causes AIDS)—to a female during intercourse with an infected male. The mucosa of the vagina contains large stores of glycogen, the decomposition of which produces organic acids. The resulting acidic environment retards microbial growth, but it also is harmful to sperm. Alkaline components of semen, mainly from the seminal vesicles, raise the pH of fluid in the vagina and increase viability of the sperm.

The muscularis is composed of an outer circular layer and an inner longitudinal layer of smooth muscle that can stretch considerably to accommodate the penis during sexual intercourse and a child during birth.

The adventitia, the superficial layer of the vagina, consists of areolar connective tissue. It anchors the vagina to adjacent organs such as the urethra and urinary bladder anteriorly and the rectum and anal canal posteriorly.

A thin fold of vascularized mucous membrane, called the hymen (= membrane), forms a border around and partially closes the inferior end of the vaginal opening to the exterior, the vaginal orifice (see Figure 28.20). After its rupture, usually following the first sexual intercourse, only remnants of the hymen remain. Sometimes the hymen completely covers the orifice, a condition called imperforate hymen (im-PER-fō-rāt). Surgery may be needed to open the orifice and permit the discharge of menstrual flow.

**Vulva**

The term vulva (VUL-va = to wrap around), or pudendum (pū-DEN-dum), refers to the external genitals of the female (Figure 28.20). The following components comprise the vulva:

- Anterior to the vaginal and urethral openings is the mons pubis (MONZ PÜ-bis; mons = mountain), an elevation of adipose tissue covered by skin and coarse pubic hair that cushions the pubic symphysis.
- From the mons pubis, two longitudinal folds of skin, the labia majora (LÄ-bē-a ma-JÖ-ra; labia = lips; majora = larger), extend inferiorly and posteriorly. The singular term is labium majus. The labia majora are covered by pubic hair and contain an abundance of adipose tissue, sebaceous (oil) glands, and apocrine sudoriferous (sweat) glands. They are homologous to the scrotum.
- Medial to the labia majora are two smaller folds of skin called the labia minora (mī-NO-ra; minora = smaller). The singular term is labium minus. Unlike the labia majora, the labia minora are devoid of pubic hair and fat and have few sudoriferous glands, but they do contain many sebaceous glands. The labia minora are homologous to the spongy (penile) urethra.
- The clitoris (KLI-to-ris) is a small cylindrical mass composed of two small erectile bodies, the corpora cavernosa, and numerous nerves and blood vessels. The clitoris is located at the anterior junction of the labia minora. A layer of skin called the prepuce of the clitoris is formed at the point where the labia minora unite and covers the body of the clitoris. The exposed portion of the clitoris is the glans clitoris. The clitoris is homologous to the glans penis in vulva.
The vulva refers to the external genitals of the female.

**Figure 28.20** Components of the vulva (pudendum).

(See Tortora, *A Photographic Atlas of the Human Body, Second Edition*, Figure 14.7.)

The vulva refers to the external genitals of the female.

(a) Inferior view

(b) Transverse section through the vaginal wall
males. Like the male structure, the clitoris is capable of enlargement upon tactile stimulation and has a role in sexual excitement in the female.

- The region between the labia minora is the **vestibule**. Within the vestibule are the hymen (if still present), the vaginal orifice, the external urethral orifice, and the openings of the ducts of several glands. The vestibule is homologous to the membranous urethra of males. The **vaginal orifice**, the opening of the vagina to the exterior, occupies the greater portion of the vestibule and is bordered by the hymen. Anterior to the vaginal orifice and posterior to the clitoris is the **external urethral orifice**, the opening of the urethra to the exterior. On either side of the external urethral orifice are the openings of the **paraurethral (Skene’s) glands**. These mucus-secreting glands are embedded in the wall of the urethra. The paraurethral glands are homologous to the prostate. On either side of the vaginal orifice itself are the **greater vestibular (Bartholin’s) glands** (see Figure 28.21), which open by ducts into a groove between the hymen and labia minora. They produce a small quantity of mucus during sexual arousal and intercourse that adds to cervical mucus and provides lubrication. The greater vestibular glands are homologous to the bulbourethral glands in males. Several **lesser vestibular glands** also open into the vestibule.

- The **bulb of the vestibule** (see Figure 28.21) consists of two elongated masses of erectile tissue just deep to the labia on either side of the vaginal orifice. The bulb of the vestibule becomes engorged with blood during sexual arousal, narrowing the vaginal orifice and placing pressure on the penis during intercourse. The bulb of the vestibule is homologous to the corpus spongiosum and bulb of the penis in males.

Table 28.2 summarizes the homologous structures of the female and male reproductive systems.

Perineum

The perineum (per’-i-NE-um) is the diamond-shaped area medial to the thighs and buttocks of both males and females (Figure 28.21). It contains the external genitals and anus. The perineum is bounded anteriorly by the pubic symphysis, laterally by the ischial tuberosities, and posteriorly by the coccyx. A transverse line drawn between the ischial tuberosities divides the perineum into an anterior urogenital triangle (u’-ro-JEN-i-tal) that contains the external genitals and a posterior anal triangle that contains the anus.

\[\text{UROGENITAL TRIANGLE}\]

\[\text{ANAL TRIANGLE}\]

\[\text{CLINICAL CONNECTION} \quad \text{Episiotomy}\]

During childbirth, the emerging fetus stretches the perineal region. To prevent excessive stretching and even tearing of this region, a physician sometimes performs an episiotomy (e-piz-e-O-T-o-my; epis- = vulva or pubic region; -otomy = incision), a perineal cut made with surgical scissors. The cut may be made along the midline or at an angle of approximately 45 degrees to the midline. In effect, a straight, more easily sutured cut is substituted for the jagged tear that would otherwise be caused by passage of the fetus. The incision is closed in layers with sutures that are absorbed within a few weeks, so that the busy new mom does not have to worry about making time to have them removed.

Mammary Glands

Each breast is a hemispheric projection of variable size anterior to the pectoralis major and serratus anterior muscles and attached to them by a layer of fascia composed of dense irregular connective tissue. Each breast has one pigmented projection, the nipple, that has a series of closely spaced openings of ducts called lactiferous ducts, where milk emerges. The circular pigmented area of skin surrounding the nipple is called the areola (a-RE-0-la = small space); it appears rough because it contains modified sebaceous (oil) glands. Strands of connective tissue called the suspensory ligaments of the breast (Cooper’s ligaments) run between the skin and fascia and support the breast. These ligaments become looser with age or with the excessive strain that can occur in long-term jogging or high-impact aerobics. Wearing a supportive bra can slow this process and help maintain the strength of the suspensory ligaments.

Within each breast is a mammary gland, a modified sudoriferous (sweat) gland that produces milk (Figure 28.22). A mammary gland consists of 15 to 20 lobes, or compartments, separated by a variable amount of adipose tissue. In each lobe are several smaller compartments called lobules, composed of grapelike clusters of milk-secreting glands termed alveoli (= small cavities) embedded in connective tissue. Contraction of

\[\text{Figure 28.21 Perineum of a female.} \quad \text{(Figure 11.13 on page 369 shows the perineum of a male.)}\]

The perineum is a diamond-shaped area that includes the urogenital triangle and the anal triangle.
Myoepithelial cells surrounding the alveoli helps propel milk toward the nipples. When milk is being produced, it passes from the alveoli into a series of secondary tubules and then into the mammary ducts. Near the nipple, the mammary ducts expand to form sinuses called lactiferous sinuses (lact- = milk), where some milk may be stored before draining into a lactiferous duct. Each lactiferous duct typically carries milk from one of the lobes to the exterior.

**Clinical Connection: Breast Augmentation and Reduction**

Breast augmentation (enlargement), technically called augmentation mammoplasty, is a surgical procedure to increase breast size and shape. It may be done to enhance breast size for females who feel that their breasts are too small, to restore breast volume due to weight loss or following pregnancy, to improve the shape of breasts that are sagging, and to improve breast appearance following surgery, trauma, or congenital abnormalities. The most commonly used implants are filled with either a saline solution or silicone gel. The incision for the implant is made under the breast, around the areola, in the armpit, or in the navel. Then a pocket is made to place the implant either directly behind the breast tissue or beneath the pectoralis major muscle.

Breast reduction or reduction mammoplasty is a surgical procedure that involves reducing breast size by removing fat, skin, and glandular tissue. This procedure is done because of chronic back, neck, and shoulder pain; poor posture; circulation or breathing problems; a skin rash under the breasts; restricted levels of activity; self-esteem problems; deep grooves in the shoulders from bra strap pressure; and difficulty wearing or fitting into certain bras and clothing. The most common procedure involves an incision around the areola, down the breast toward the crease between the breast and abdomen, and then along the crease. The surgeon removes excess tissue through the incisions. In most cases, the nipple and areola remain attached to the breast. However, if the breasts are extremely large, the nipple and areola may have to be reattached at a higher position.

The functions of the mammary glands are the synthesis, secretion, and ejection of milk; these functions, called lactation, are associated with pregnancy and childbirth. Milk production is stimulated largely by the hormone prolactin from the anterior pituitary, with contributions from progesterone and estrogens. The ejection of milk is stimulated by oxytocin, which is released from the posterior pituitary in response to the sucking of an infant on the mother’s nipple (suckling).

**Figure 28.22** Mammary glands within the breasts. (See Tortora, *A Photographic Atlas of the Human Body, Second Edition*, Figure 14.14.)

The mammary glands function in the synthesis, secretion, and ejection of milk (lactation).

**Question:** What hormones regulate the synthesis and ejection of milk?
CHAPTER 28

THE REPRODUCTIVE SYSTEMS

Fibrocystic Disease of the Breasts

The breasts of females are highly susceptible to cysts and tumors. In fibrocystic disease, the most common cause of breast lumps in females, one or more cysts (fluid-filled sacs) and thickenings of alveoli develop. The condition, which occurs mainly in females between the ages of 30 and 50, is probably due to a relative excess of estrogens or a deficiency of progesterone in the postovulatory (luteal) phase of the reproductive cycle (discussed shortly). Fibrocystic disease usually causes one or both breasts to become lumpy, swollen, and tender a week or so before menstruation begins.

CHECKPOINT

22. How does the histology of the vagina contribute to its function?
23. What are the structures and functions of each part of the vulva?
24. Describe the components of the mammary glands and the structures that support them.
25. Outline the route milk takes from the alveoli of the mammary gland to the nipple.

THE FEMALE REPRODUCTIVE CYCLE

OBJECTIVE

• Compare the major events of the ovarian and uterine cycles.

During their reproductive years, nonpregnant females normally exhibit cyclical changes in the ovaries and uterus. Each cycle takes about a month and involves both oogenesis and preparation of the uterus to receive a fertilized ovum. Hormones secreted by the hypothalamus, anterior pituitary, and ovaries control the main events. The ovarian cycle is a series of events in the ovaries that occur during and after the maturation of an oocyte. The uterine (menstrual) cycle is a concurrent series of changes in the endometrium of the uterus to prepare it for the arrival of a fertilized ovum that will develop there until birth. If fertilization does not occur, ovarian hormones wane, which causes the stratum functionalis of the endometrium to slough off. The general term female reproductive cycle encompasses the ovarian and uterine cycles, the hormonal changes that regulate them, and the related cyclical changes in the breasts and cervix.

Hormonal Regulation of the Female Reproductive Cycle

Gonadotropin-releasing hormone (GnRH) secreted by the hypothalamus controls the ovarian and uterine cycles (Figure 28.23). GnRH stimulates the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. FSH initiates follicular growth, while LH stimulates further development of the ovarian follicles. In addition, both FSH and LH stimulate the ovarian follicles to secrete estrogens. LH stimulates the theca cells of a developing follicle to produce androgens. Under the influence of FSH, the androgens are taken up by the granulosa cells of the follicle and then converted into estrogens. At midcycle, LH triggers ovulation and then promotes formation of the corpus luteum, the reason for the name luteinizing hormone. Stimulated by LH, the corpus luteum produces and secretes estrogens, progesterone, relaxin, and inhibin.

At least six different estrogens have been isolated from the plasma of human females, but only three are present in significant quantities: beta (β)-estradiol, estrone, and estriol. In a nonpregnant woman, the most abundant estrogen is β-estradiol, which is synthesized from cholesterol in the ovaries.

Estrogens secreted by ovarian follicles have several important functions (Figure 28.23).

• Estrogens promote the development and maintenance of female reproductive structures, secondary sex characteristics, and the breasts. The secondary sex characteristics include distribution of adipose tissue in the breasts, abdomen, mons pubis, and hips; voice pitch; a broad pelvis; and pattern of hair growth on the head and body.
• Estrogens increase protein anabolism, including the building of strong bones. In this regard, estrogens are synergistic with human growth hormone (hGH).
• Estrogens lower blood cholesterol level, which is probably the reason that women under age 50 have a much lower risk of coronary artery disease than do men of comparable age.
• Moderate levels of estrogens in the blood inhibit both the release of GnRH by the hypothalamus and secretion of LH and FSH by the anterior pituitary.

Progesterone, secreted mainly by cells of the corpus luteum, cooperates with estrogens to prepare and maintain the endometrium for implantation of a fertilized ovum and to prepare the mammary glands for milk secretion. High levels of progesterone also inhibit secretion of GnRH and LH.

The small quantity of relaxin produced by the corpus luteum during each monthly cycle relaxes the uterus by inhibiting contractions of the myometrium. Presumably, implantation of a fertilized ovum occurs more readily in a “quiet” uterus. During pregnancy, the placenta produces much more relaxin, and it continues to relax uterine smooth muscle. At the end of pregnancy, relaxin also increases the flexibility of the pubic symphysis and may help dilate the uterine cervix, both of which ease delivery of the baby.

Inhibin is secreted by granulosa cells of growing follicles and by the corpus luteum after ovulation. It inhibits secretion of FSH and, to a lesser extent, LH.

Phases of the Female Reproductive Cycle

The duration of the female reproductive cycle typically ranges from 24 to 35 days. For this discussion, we assume a duration of 28 days and divide it into four phases: the menstrual phase, the preovulatory phase, ovulation, and the postovulatory phase (Figure 28.24 on page 1114).
Figure 28.23  Secretion and physiological effects of estrogens, progesterone, relaxin, and inhibin in the female reproductive cycle. Dashed red lines indicate negative feedback inhibition.

The uterine and ovarian cycles are controlled by gonadotropin-releasing hormone (GnRH) and ovarian hormones (estrogens and progesterone).

**Menstrual Phase**

The **menstrual phase** (MEN-stroo-al), also called menstruation (men’-stroo-Á-shun) or **menses** (MEN-séz = month), lasts for roughly the first 5 days of the cycle. (By convention, the first day of menstruation is day one of a new cycle.)

**Events in the Ovaries**  Under the influence of FSH, several primordial follicles develop into primary follicles and then into secondary follicles. This developmental process may take several months to occur. Therefore, a follicle that begins to develop at the beginning of a particular menstrual cycle may not reach maturity and ovulate until several menstrual cycles later.

**Events in the Uterus**  Menstrual flow from the uterus consists of 50–150 mL of blood, tissue fluid, mucus, and epithelial cells shed from the endometrium. This discharge occurs because the declining levels of progesterone and estrogens stimulate release of prostaglandins that cause the uterine spiral arterioles to constrict. As a result, the cells they supply become oxygen-deprived and start to die. Eventually, the entire stratum functionalis sloughs off. At this time the endometrium is very thin, about 2–5 mm, because only the stratum basalis remains. The menstrual flow passes from the uterine cavity through the cervix and vagina to the exterior.

**Preovulatory Phase**

The **preovulatory phase** is the time between the end of menstruation and ovulation. The preovulatory phase of the cycle is more variable in length than the other phases and accounts for most of the differences in length of the cycle. It lasts from days 6 to 13 in a 28-day cycle.

**Events in the Ovaries**  Some of the secondary follicles in the ovaries begin to secrete estrogens and inhibin. By about day 6, a single secondary follicle in one of the two ovaries has outgrown all the others to become the **dominant follicle**. Estrogens and inhibin secreted by the dominant follicle decrease the secretion of FSH, which causes other, less well-developed follicles to stop growing and undergo atresia. Fraternal (nonidentical) twins or triplets result when two or three secondary follicles become codominant and later are ovulated and fertilized at about the same time.
Figure 28.24 The female reproductive cycle. The length of the female reproductive cycle typically is 24 to 36 days; the preovulatory phase is more variable in length than the other phases. (a) Events in the ovarian and uterine cycles and the release of anterior pituitary hormones are correlated with the sequence of the cycle’s four phases. In the cycle shown, fertilization and implantation have not occurred. (b) Relative concentrations of anterior pituitary hormones (FSH and LH) and ovarian hormones (estrogens and progesterone) during the phases of a normal female reproductive cycle.

Estrogens are the primary ovarian hormones before ovulation; after ovulation, both progesterone and estrogens are secreted by the corpus luteum.

Which hormones are responsible for the proliferative phase of endometrial growth, for ovulation, for growth of the corpus luteum, and for the surge of LH at midcycle?
Normally, the one dominant secondary follicle becomes the mature (graafian) follicle, which continues to enlarge until it is more than 20 mm in diameter and ready for ovulation (see Figure 28.13). This follicle forms a blisterlike bulge due to the swelling antrum on the surface of the ovary. During the final maturation process, the mature follicle continues to increase its production of estrogens (Figure 28.24).

With reference to the ovarian cycle, the menstrual and preovulatory phases together are termed the follicular phase (fölik-ū-lär) because ovarian follicles are growing and developing.

**EVENTS IN THE UTERUS** Estrogens liberated into the blood by growing ovarian follicles stimulate the repair of the endometrium; cells of the stratum basalis undergo mitosis and produce a new stratum functionalis. As the endometrium thickens, the short, straight endometrial glands develop, and the arterioles coil and lengthen as they penetrate the stratum functionalis. The thickness of the endometrium approximately doubles, to about 4–10 mm. With reference to the uterine cycle, the preovulatory phase is also termed the proliferative phase because the endometrium is proliferating.

**Ovulation**

Ovulation, the rupture of the mature (graafian) follicle and the release of the secondary oocyte into the pelvic cavity, usually occurs on day 14 in a 28-day cycle. During ovulation, the secondary oocyte remains surrounded by its zona pellucida and corona radiata.

The high levels of estrogens during the last part of the preovulatory phase exert a positive feedback effect on the cells that secrete LH and gonadotropin-releasing hormone (GnRH) and cause ovulation, as follows (Figure 28.25):

1. A high concentration of estrogens stimulates more frequent release of GnRH from the hypothalamus. It also directly stimulates gonadotrophs in the anterior pituitary to secrete LH.
2. GnRH promotes the release of FSH and additional LH by the anterior pituitary.
3. LH causes rupture of the mature (graafian) follicle and expulsion of a secondary oocyte about 9 hours after the peak of the LH surge. The ovulated oocyte and its corona radiata cells are usually swept into the uterine tube.

From time to time, an oocyte is lost into the pelvic cavity, where it later disintegrates. The small amount of blood that sometimes leaks into the pelvic cavity from the ruptured follicle can cause pain, known as mittelschmerz (MIT-el-shmärts = pain in the middle), at the time of ovulation.

An over-the-counter home test that detects a rising level of LH can be used to predict ovulation a day in advance.

**Postovulatory Phase**

The postovulatory phase of the female reproductive cycle is the time between ovulation and onset of the next menses. In duration, it is the most constant part of the female reproductive cycle.

It lasts for 14 days in a 28-day cycle, from day 15 to day 28 (see Figure 28.24).

**EVENTS IN ONE OVARY** After ovulation, the mature follicle collapses, and the basement membrane between the granulosa cells and theca interna breaks down. Once a blood clot forms from minor bleeding of the ruptured follicle, the follicle becomes the corpus hemorrhagicum (hemo- = blood; rrhagic- = bursting forth) (see Figure 28.13). Theca interna cells mix with the granulosa cells as they all become transformed into corpus luteum cells under the influence of LH. Stimulated by LH, the corpus luteum secretes progesterone, estrogen, relaxin, and inhibin. The luteal cells also absorb the blood clot. With reference to the ovarian cycle, this phase is also called the luteal phase.

Later events in an ovary that has ovulated an oocyte depend on whether the oocyte is fertilized. If the oocyte is not fertilized, the corpus luteum has a lifespan of only 2 weeks. Then, its secretory activity declines, and it degenerates into a corpus albicans (see Figure 28.13). As the levels of progesterone, estrogens, and inhibin decrease, release of GnRH, FSH, and LH rises due to loss of negative feedback suppression by the ovarian hormones. Follicular growth resumes and a new ovarian cycle begins.

If the secondary oocyte is fertilized and begins to divide, the corpus luteum persists past its normal 2-week lifespan. It is...
“rescued” from degeneration by human chorionic gonadotropin (kō-rē-ON-ik) (hCG). This hormone is produced by the chorion of the embryo beginning about 8 days after fertilization. Like LH, hCG stimulates the secretory activity of the corpus luteum. The presence of hCG in maternal blood or urine is an indicator of pregnancy and is the hormone detected by home pregnancy tests.

**Events in the Uterus** Progesterone and estrogens produced by the corpus luteum promote growth and coiling of the endometrial glands, vascularization of the superficial endometrium, and thickening of the endometrium to 12–18 mm (0.48–0.72 in.). Because of the secretory activity of the endometrial glands, which begin to secrete glycogen, this period is called the secretory phase of the uterine cycle. These preparatory changes peak about one week after ovulation, at the time a fertilized ovum might arrive in the uterus. If fertilization does not occur, the levels of progesterone and estrogens decline due to degeneration of the corpus luteum. Withdrawal of progesterone and estrogens causes menstruation.

Figure 28.26 summarizes the hormonal interactions and cyclic changes in the ovaries and uterus during the ovarian and uterine cycles.

When declining levels of estrogens and progesterone stimulate secretion of GnRH, is this a positive or a negative feedback effect? Why?
ABORTION

BIRTH CONTROL METHODS AND ABORTION

**Objective**
- Explain the differences among the various types of birth control methods and compare their effectiveness.

Birth control refers to restricting the number of children by various methods designed to control fertility and prevent conception. No single, ideal method of birth control exists. The only method of preventing pregnancy that is 100% reliable is complete abstinence, the avoidance of sexual intercourse. Several other methods are available; each has its advantages and disadvantages. These include surgical sterilization, hormonal methods, intrauterine devices, spermicides, barrier methods, and periodic abstinence. Table 28.3 provides the failure rates for various methods of birth control. Although it is not a form of birth control, in this section we will also discuss abortion, the premature expulsion of the products of conception from the uterus.

**Surgical Sterilization**

Sterilization is a procedure that renders an individual incapable of further reproduction. The principal method for sterilization of males is a vasectomy (described in the Clinical Connection on page 1091). Sterilization in females most often is achieved by performing a tubal ligation (İ-GA-shun), in which both uterine tubes are tied closed and then cut. This can be achieved in a few

† Failure rate when the method is used correctly and consistently.
different ways. “Clips” or “clamps” can be placed on the uterine tubes, the tubes can be tied and/or cut, and sometimes they are cauterized. In any case the result is that the secondary oocyte cannot pass through the uterine tubes, and sperm cannot reach the oocyte. Tubal ligation reduces the risk of pelvic inflammatory disease in women who are exposed to sexually transmitted infections; it may also reduce the risk of ovarian cancer.

Hormonal Methods

Aside from complete abstinence or surgical sterilization, hormonal methods are the most effective means of birth control. Oral contraceptives (the pill) contain hormones designed to prevent pregnancy. Some, called combined oral contraceptives (COCs), contain both progestin (hormone with actions similar to progesterone) and estrogens. The primary action of COCs is to inhibit ovulation by suppressing the gonadotropins FSH and LH. The low levels of FSH and LH usually prevent the development of a dominant follicle in the ovary. As a result, levels of estrogens do not rise, the midcycle LH surge does not occur, and ovulation does not take place. Even if ovulation does occur, as it does in some cases, COCs may also block implantation in the uterus and inhibit the transport of ova and sperm in the uterine tubes.

Progestins thicken cervical mucus and make it more difficult for sperm to enter the uterus. Progestin-only pills thicken cervical mucus and may block implantation in the uterus, but they do not consistently inhibit ovulation.

Among the noncontraceptive benefits of oral contraceptives are regulation of the length of menstrual cycle and decreased menstrual flow (and therefore decreased risk of anemia). The pill also provides protection against endometrial and ovarian cancers and reduces the risk of endometriosis. However, oral contraceptives may not be advised for women with a history of blood clotting disorders, cerebral blood vessel damage, migraine headaches, hypertension, liver malfunction, or heart disease. Women who take the pill and smoke face far higher odds of having a heart attack or stroke than do nonsmoking pill users. Smokers should quit smoking or use an alternative method of birth control.

Among the noncontraceptive benefits of oral contraceptives are inhibition of ovulation, menstrual suppression, prevention of endometriosis, and possibly the prevention of endometrial and ovarian cancers. However, oral contraceptives do not consistently inhibit ovulation. Progestin-only pills thicken cervical mucus and may block implantation in the uterus, but they do not consistently inhibit ovulation.

Non-oral hormonal methods of contraception are also available. Among these are the following:

- **Combined pill.** Contains both progestin and estrogens and is typically taken once a day for three weeks to prevent pregnancy and regulate the menstrual cycle. The pills taken during the fourth week are inactive (do not contain hormones) and prevent menstruation to occur.
- **Seasonale®.** Contains both progestin and estrogens and is taken once a day in 3-month cycles of 12 weeks of hormone-containing pills followed by one week of inactive pills. Menstruation occurs during the thirteenth week.
- **Minipill.** Contains progestin only and is taken every day of the month.
- **Contraceptive skin patch (Ortho Evra®).** Contains both progestin and estrogens delivered in a skin patch placed on the skin (upper outer arm, back, lower abdomen, or buttocks) once a week for three weeks. After one week, the patch is removed from one location and then a new one is placed elsewhere. During the fourth week no patch is used.
- **Vaginal contraceptive ring (NuvaRing®).** A flexible doughnut-shaped ring about 5 cm (2 in.) in diameter that contains estrogens and progesterone and is inserted by the female herself into the vagina. It is left in the vagina for three weeks to prevent conception and then removed for one week to permit menstruation.
- **Emergency contraception (EC) (morning after pill).** Consists of progestin and estrogens or progestin alone to prevent pregnancy following unprotected sexual intercourse. The relatively high levels of progestin and estrogens in EC pills provide inhibition of FSH and LH secretion. Loss of the stimulating effects of these gonadotropic hormones causes the ovaries to cease secretion of their own estrogens and progesterone. In turn, declining levels of estrogens and progesterone induce shedding of the uterine lining, thereby blocking implantation. One pill is taken as soon as possible but within 72 hours of unprotected sexual intercourse. The second pill must be taken 12 hours after the first. The pills work in the same way as regular birth control pills.
- **Hormone injections (Depo-provera®).** An injectable progestin given intramuscularly by a health-care practitioner once every three months.

**Intrauterine Devices**

An **intrauterine device (IUD)** is a small object made of plastic, copper, or stainless steel that is inserted by a health-care professional into the cavity of the uterus. IUDs prevent fertilization from taking place by blocking sperm from entering the uterine tubes. The IUD most commonly used in the United States today is the Copper T 380A®, which is approved for up to 10 years of use and has long-term effectiveness comparable to that of tubal ligation. Some women cannot use IUDs because of expulsion, bleeding, or discomfort.

**Spermicides**

Various foams, creams, jellies, suppositories, and douches that contain sperm-killing agents, or **spermicides**, make the vagina and cervix unfavorable for sperm survival and are available without prescription. They are placed in the vagina before sexual intercourse. The most widely used spermicide is **nonoxynol-9**, which kills sperm by disrupting their plasma membranes. A spermicide is more effective when used with a barrier method such as a male condom, vaginal pouch, diaphragm, or cervical cap.

**Barrier Methods**

**Barrier methods** use a physical barrier and are designed to prevent sperm from gaining access to the uterine cavity and uterine tubes. In addition to preventing pregnancy, certain barrier
methods (male condom and vaginal pouch) may also provide some protection against sexually transmitted diseases (STDs) such as AIDS. In contrast, oral contraceptives and IUDs confer no such protection. Among the barrier methods are the male condom, vaginal pouch, diaphragm, and cervical cap.

A **male condom** is a nonporous, latex covering placed over the penis that prevents deposition of sperm in the female reproductive tract. A **vaginal pouch**, sometimes called a **female condom**, is designed to prevent sperm from entering the uterus. It is made of two flexible rings connected by a polyurethane sheath. One ring lies inside the sheath and is inserted to fit over the cervix; the other ring remains outside the vagina and covers the female external genitals. A **diaphragm** is a rubber, dome-shaped structure that fits over the cervix and is used in conjunction with a spermicide. It can be inserted by the female up to 6 hours before intercourse. The diaphragm stops most sperm from passing into the cervix and the spermicide kills most sperm that do get by. Although diaphragm use does decrease the risk of some STDs, it does not fully protect against HIV infection because the vagina is still exposed. A **cervical cap** resembles a diaphragm but is smaller and more rigid. It fits snugly over the cervix and must be fitted by a health-care professional. Spermicides should be used with the cervical cap.

**Periodic Abstinence**

A couple can use their knowledge of the physiological changes that occur during the female reproductive cycle to decide either to abstain from intercourse on those days when pregnancy is a likely result, or to plan intercourse on those days if they wish to conceive a child. In females with normal and regular menstrual cycles, these physiological events help to predict the day on which ovulation is likely to occur.

The first physiologically based method, developed in the 1930s, is known as the **rhythm method**. It involves abstaining from sexual activity on the days that ovulation is likely to occur in each reproductive cycle. During this time (3 days before ovulation, the day of ovulation, and 3 days after ovulation) the couple abstains from intercourse. The effectiveness of the rhythm method for birth control is poor in many women due to the irregularity of the female reproductive cycle.

Another system is the **sympto-thermal method**, in which couples are instructed to know and understand certain signs of fertility. The signs of ovulation include increased basal body temperature; the production of abundant clear, stretchy cervical mucus; and pain associated with ovulation (**mittelschmerz**). If a couple abstains from sexual intercourse when the signs of ovulation are present and for 3 days afterward, the chance of pregnancy is decreased. A big problem with this method is that fertilization is very likely if intercourse occurs one or two days **before** ovulation.

**Abortion**

**Abortion** refers to the premature expulsion of the products of conception from the uterus, usually before the twentieth week of pregnancy. An abortion may be **spontaneous** (naturally occurring; also called a miscarriage) or **induced** (intentionally performed).

There are several types of induced abortions. One involves **mifepristone**, called **miniprex** in the United States and **RU 486** in Europe. It is a hormone approved only for pregnancies 9 weeks or less when taken with misoprostol (a prostaglandin).

Mifepristone is an antiprogestin; it blocks the action of progestosterone by binding to and blocking progesterone receptors. Progesterone prepares the uterine endometrium for implantation and then maintains the uterine lining after implantation. If the level of progesterone falls during pregnancy or if the action of the hormone is blocked, menstruation occurs, and the embryo sloughs off along with the uterine lining. Within 12 hours after taking mifepristone, the endometrium starts to degenerate, and within 72 hours it begins to slough off. Misoprostol stimulates uterine contractions, and is given after mifepristone to aid in expulsion of the endometrium.

Another type of induced abortion is called **vacuum aspiration** (suction) and can be performed up to the sixteenth week of pregnancy. A small, flexible tube attached to a vacuum source is inserted into the uterus through the vagina. The embryo or fetus, placenta, and lining of the uterus are then removed by suction. For pregnancies between 13 and 16 weeks, a technique called **dilation and evacuation** is commonly used. After the cervix is dilated, suction and forceps are used to remove the fetus, placenta, and uterine lining. From the 16th to 24th week, a **late-stage abortion** may be employed using surgical methods similar to dilation and evacuation or through nonsurgical methods using a saline solution or medications to induce abortion. Labor may be induced by using vaginal suppositories, intravenous infusion, or injections into the amniotic fluid through the uterus.

**CHECKPOINT**

29. How do oral contraceptives reduce the likelihood of pregnancy?

30. How do some methods of birth control protect against sexually transmitted diseases?

31. What is the problem with developing an oral contraceptive pill for males?
The gonads develop from intermediate mesoderm.

**Which gene is responsible for the development of the gonads into testes?**
mesonephric ducts and eventually form structures of the reproductive system in females. Both sets of ducts empty into the urogenital sinus. An early embryo has the potential to follow either the male or the female pattern of development because it contains both sets of ducts and primitive gonads that can differentiate into either testes or ovaries.

Cells of a male embryo have one X chromosome and one Y chromosome. The male pattern of development is initiated by a “master switch” gene on the Y chromosome named SRY, which stands for Sex-determining Region of the Y chromosome. When the SRY gene is expressed during development, its protein product causes the primitive Sertoli cells to begin to differentiate in the gonadal tissues during the seventh week. The developing Sertoli cells secrete a hormone called Müllerian-inhibiting hormone (MIH), which causes apoptosis of cells within the paramesonephric (Müllerian) ducts. As a result, those cells do not contribute any functional structures to the male reproductive system. Stimulated by human chorionic gonadotropin (hCG), primitive Leydig cells in the gonadal tissue begin to secrete the androgen testosterone during the eighth week. Testosterone then stimulates development of the mesonephric duct on each side into the epididymis, ductus (vas) deferens, ejaculatory duct, and seminal vesicle. The testes connect to the mesonephric duct through a series of tubules that eventually become the seminiferous tubules. The prostate and bulbourethral glands are endodermal outgrowths of the urethra.

Cells of a female embryo have two X chromosomes and no Y chromosome. Because SRY is absent, the gonads develop into ovaries, and because MIH is not produced, the paramesonephric ducts flourish. The distal ends of the paramesonephric ducts fuse to form the uterus and vagina; the unfused proximal portions of the ducts become the uterine (fallopian) tubes. The mesonephric ducts degenerate without contributing any functional structures to the female reproductive system because of the absence of testosterone. The greater and lesser vestibular glands develop from endodermal outgrowths of the vestibule.

The external genitals of both male and female embryos (penis and scrotum in males and clitoris, labia, and vaginal orifice in females) also remain undifferentiated until about the eighth week. Before differentiation, all embryos have an elevated midline swelling called the genital tubercle (Figure 28.28). The tubercle consists of the urethral groove (opening into the urogenital sinus), paired urethral folds, and paired labioscrotal swellings.

In male embryos, some testosterone is converted to a second androgen called dihydrotestosterone (DHT). DHT stimulates development of the urethra, prostate, and external genitals (scrotum and penis).
Part of the genital tubercle elongates and develops into a penis. Fusion of the urethral folds forms the spongy (penile) urethra and leaves an opening to the exterior only at the distal end of the penis, the external urethral orifice. The labioscrotal swellings develop into the scrotum. In the absence of DHT, the genital tubercle gives rise to the clitoris in female embryos. The urethral folds remain open as the labia minora, and the labioscrotal swellings become the labia majora. The urethral groove becomes the vestibule. After birth, androgen levels decline because hCG is no longer present to stimulate secretion of testosterone.

**Checkpoint**

32. Describe the role of hormones in differentiation of the gonads, the mesonephric ducts, the paramesonephric ducts, and the external genitals.

### AGING AND THE REPRODUCTIVE SYSTEMS

**Objective**

- Describe the effects of aging on the reproductive systems.

During the first decade of life, the reproductive system is in a juvenile state. At about age 10, hormone-directed changes start to occur in both sexes. Puberty (PÜ-ber-tē = a ripe age) is the period when secondary sexual characteristics begin to develop and the potential for sexual reproduction is reached. The onset of puberty is marked by pulses or bursts of LH and FSH secretion, each triggered by a pulse of GnRH. Most pulses occur during sleep. As puberty advances, the hormone pulses occur during the day as well as at night. The pulses increase in frequency during a three- to four-year period until the adult pattern is established. The stimuli that cause the GnRH pulses are still unclear, but a role for the hormone leptin is starting to unfold. Just before puberty, leptin levels rise in proportion to adipose tissue mass. Interestingly, leptin receptors are present in both the hypothalamus and anterior pituitary. Mice that lack a functional leptin gene from birth are sterile and remain in a prepubertal state. Giving leptin to such mice elicits secretion of gonadotropins, and they become fertile. Leptin may signal the hypothalamus that long-term energy stores (triglycerides in adipose tissue) are adequate for reproductive functions to begin.

In females, the reproductive cycle normally occurs once each month from menarche (me-NAR-kē), the first menses, to menopause, the permanent cessation of menses. Thus, the female reproductive system has a time-limited span of fertility between menarche and menopause. For the first 1 to 2 years after menarche, ovulation only occurs in about 10% of the cycles and the luteal phase is short. Gradually, the percentage of ovulatory cycles increases, and the luteal phase reaches its normal duration of 14 days. With age, fertility declines. Between the ages of 40 and 50 the pool of remaining ovarian follicles becomes exhausted. As a result, the ovaries become less responsive to hormonal stimulation. The production of estrogens declines, despite copious secretion of FSH and LH by the anterior pituitary. Many women experience hot flashes and heavy sweating, which coincide with bursts of GnRH release. Other symptoms of menopause are headache, hair loss, muscular pains, vaginal dryness, insomnia, depression, weight gain, and mood swings. Some atrophy of the ovaries, uterine tubes, uterus, vagina, external genitalia, and breasts occurs in postmenopausal women. Due to loss of estrogens, most women experience a decline in bone mineral density after menopause. Sexual desire (libido) does not show a parallel decline; it may be maintained by adrenal sex steroids. The risk of having uterine cancer peaks at about 65 years of age, but cervical cancer is more common in younger women.

In males, declining reproductive function is much more subtle than in females. Healthy men often retain reproductive capacity into their eighties or nineties. At about age 55 a decline in testosterone synthesis leads to reduced muscle strength, fewer viable sperm, and decreased sexual desire. Although sperm production decreases 50–70% between ages 60 and 80, abundant sperm may still be present even in old age.

Enlargement of the prostate to two to four times its normal size occurs in most males over age 60. This condition, called benign prostatic hyperplasia (BPH), decreases the size of the prostatic urethra and is characterized by frequent urination, nocturia (bed-wetting), hesitancy in urination, decreased force of urinary stream, postvoiding dribbling, and a sensation of incomplete emptying.

**Checkpoint**

33. What changes occur in males and females at puberty?

34. What do the terms menarche and menopause mean?

To appreciate the many ways that the reproductive systems contribute to homeostasis of other body systems, examine *Focus on Homeostasis: The Reproductive Systems*. Next, in Chapter 29, you will explore the major events that occur during pregnancy and you will discover how genetics (inheritance) plays a role in the development of a child.

Reproductive System Disorders in Males

Testicular Cancer

Testicular cancer is the most common cancer in males between the ages of 20 and 35. More than 95% of testicular cancers arise from spermatogenic cells within the seminiferous tubules. An early sign of testicular cancer is a mass in the testis, often associated with a sensation of testicular heaviness or a dull ache in the lower abdomen; pain usually does not occur. To increase the chance for early detection of a testicular cancer, all males should perform regular self-examinations of the testes. The examination should be done starting in the teen years and once each month thereafter. After a warm bath or shower (when the scrotal skin is loose and relaxed) each testicle should be examined as follows. The testicle is grasped and gently rolled between the index finger and thumb, feeling for lumps, swellings, hardness, or other changes. If a lump or other change is detected, a physician should be consulted as soon as possible.

Prostate Disorders

Because the prostate surrounds part of the urethra, any infection, enlargement, or tumor can obstruct the flow of urine. Acute and chronic infections of the prostate are common in postpubescent males, often in association with inflammation of the urethra. Symptoms may include fever, chills, urinary frequency, frequent urination at night, difficulty in urinating, burning or painful urination, low back pain, joint and muscle pain, blood in the urine, or painful ejaculation. However, often there are no symptoms. Antibiotics are used to treat most cases that result from a bacterial infection. In acute prostatitis, the prostate becomes swollen and tender. Chronic prostatitis is one of the most common chronic infections in men of the middle and later years. On examination, the prostate feels enlarged, soft, and very tender, and its surface outline is irregular.

Prostate cancer is the leading cause of death from cancer in men in the United States, having surpassed lung cancer in 1991. Each year it is diagnosed in almost 200,000 U.S. men and causes nearly 40,000 deaths. The amount of PSA (prostate-specific antigen), which is produced only by prostate epithelial cells, increases with enlargement of the prostate and may indicate infection, benign enlargement, or prostate cancer. A blood test can measure the level of PSA in the blood. Males over the age of 40 should have an annual examination of the prostate gland. In a digital rectal exam, a physician palpates the gland through the rectum with the fingers (digits). Many physicians also recommend an annual PSA test for males over age 50. Treatment for prostate cancer may involve surgery, cryotherapy, radiation, hormonal therapy, and chemotherapy. Because many prostate cancers grow very slowly, some urologists recommend “watchful waiting” before treating small tumors in men over age 70.

Erectile Dysfunction

Erectile dysfunction (ED), previously termed impotence, is the consistent inability of an adult male to ejaculate or to attain or hold an erection long enough for sexual intercourse. Many cases of impotence are caused by insufficient release of nitric oxide (NO), which relaxes the smooth muscle of the penile arteries and erectile tissue. The drug Viagra® (sildenafil) enhances smooth muscle relaxation by nitric oxide in the penis. Other causes of erectile dysfunction include diabetes mellitus, physical abnormalities of the penis, systemic disorders such as syphilis, vascular disturbances (arterial or venous obstructions), neurological disorders, surgery, testosterone deficiency, and drugs (alcohol, antidepressants, antihistamines, antihypertensives, narcotics, nicotine, and tranquilizers). Psychological factors such as anxiety or depression, fear of causing pregnancy, fear of sexually transmitted diseases, religious inhibitions, and emotional immaturity may also cause ED.

Reproductive System Disorders in Females

Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Premenstrual syndrome (PMS) is a cyclical disorder of severe physical and emotional distress. It appears during the postovulatory (luteal) phase of the female reproductive cycle and dramatically disappears when menstruation begins. The signs and symptoms are highly variable from one woman to another. They may include edema, weight gain, breast swelling and tenderness, abdominal distension, backache, joint pain, constipation, skin eruptions, fatigue and lethargy, greater need for sleep, depression or anxiety, irritability, mood swings, headache, poor coordination and clumsiness, and cravings for sweet or salty foods. The cause of PMS is unknown. For some women, getting regular exercise; avoiding caffeine, salt, and alcohol; and eating a diet that is high in complex carbohydrates and lean proteins can bring considerable relief.

Premenstrual dysphoric disorder (PMDD) is a more severe syndrome in which PMS-like signs and symptoms do not resolve after the onset of menstruation. Clinical research studies have found that suppression of the reproductive cycle by a drug that interferes with GnRH (leuprolide) decreases symptoms significantly. Because symptoms reappear when estradiol or progesterone is given together with leuprolide, researchers propose that PMDD is caused by abnormal responses to normal levels of these ovarian hormones. SSRIs (selective serotonin receptor inhibitors) have shown promise in treating both PMS and PMDD.

Endometriosis

Endometriosis (en-dō-mē-trē-ō-sis; endo- = within; metri- = uterus; osis = condition) is characterized by the growth of endometrial tissue outside the uterus. The tissue enters the pelvic cavity via the open uterine tubes and may be found in any of several sites—on the ovaries, the rectouterine pouch, the outer surface of the uterus, the sigmoid colon, pelvic and abdominal lymph nodes, the cervix, the abdominal wall, the kidneys, and the urinary bladder. Endometrial tissue responds to hormonal fluctuations, whether it is inside or outside the uterus. With each reproductive cycle, the tissue proliferates and then breaks down and bleeds. When this occurs outside the uterus, it can cause inflammation, pain, scarring, and infertility. Symptoms include premenstrual pain or unusually severe menstrual pain.

Breast Cancer

One in eight women in the United States faces the prospect of breast cancer. After lung cancer, it is the second-leading cause of death from cancer in U.S. women. Breast cancer can occur in males but is rare. In females, breast cancer is seldom seen before age 30; its incidence rises rapidly after menopause. An estimated 5% of the 180,000 cases diagnosed each year in the United States, particularly those that arise in younger women, stem from inherited genetic mutations (changes in the DNA). Researchers have now identified two genes that increase susceptibility to breast cancer: BRCA1 (breast cancer 1) and BRCA2. Mutations of BRCA1 also confers a high risk for ovarian cancer. In addition, mutations of the p53 gene increase the risk of breast cancer in both males and females, and mutations of the androgen receptor gene
are associated with the occurrence of breast cancer in some males. Because breast cancer generally is not painful until it becomes quite advanced, any lump, no matter how small, should be reported to a physician at once. Early detection—by breast self-examination and mammograms—is the best way to increase the chance of survival.

The most effective technique for detecting tumors less than 1 cm (0.4 in.) in diameter is mammography (mam-OG-ra-fē; -graphy = to record), a type of radiography using very sensitive x-ray film. The image of the breast, called a mammogram (see Table 1.3 on page 21), is best obtained by compressing the breasts, one at a time, using flat plates. A supplementary procedure for evaluating breast abnormalities is ultrasound. Although ultrasound cannot detect tumors smaller than 1 cm in diameter (which mammography can detect), it can be used to determine whether a lump is a benign, fluid-filled cyst or a solid (and therefore possibly malignant) tumor.

Among the factors that increase the risk of developing breast cancer are (1) a family history of breast cancer, especially in a mother or sister; (2) nulliparity (never having borne a child) or having a first child after age 35; (3) previous cancer in one breast; (4) exposure to ionizing radiation, such as x-rays; (5) excessive alcohol intake; and (6) cigarette smoking.

The American Cancer Society recommends the following steps to help diagnose breast cancer as early as possible:

- All women over 20 should develop the habit of monthly breast self-examination.
- A physician should examine the breasts every 3 years when a woman is between the ages of 20 and 40, and every year after age 40.
- A mammogram should be taken in women between the ages of 35 and 39, to be used later for comparison (baseline mammogram).
- Women with no symptoms should have a mammogram every year after age 40.
- Women of any age with a history of breast cancer, a strong family history of the disease, or other risk factors should consult a physician to determine a schedule for mammography.

Treatment for breast cancer may involve hormone therapy, chemotherapy, radiation therapy, lumpectomy (removal of the tumor and the immediate surrounding tissue), a modified or radical mastectomy, or a combination of these approaches. A radical mastectomy (mast-ē = breast) involves removal of the affected breast along with the underlying pectoral muscles and the axillary lymph nodes. (Lymph nodes are removed because metastasis of cancerous cells usually occurs through lymphatic or blood vessels.) Radiation treatment and chemotherapy may follow the surgery to ensure the destruction of any stray cancer cells. Several types of chemotherapeutic drugs are used to decrease the risk of relapse or disease progression. Nolvadex® (tamoxifen) is an estrogen antagonist that binds to and blocks estrogen receptors, thus decreasing the stimulating effect of estrogen on breast cancer cells. Tamoxifen has been used for 20 years and greatly reduces the risk of cancer recurrence. Herceptin®, a monoclonal antibody drug, targets an antigen on the surface of breast cancer cells. It is effective in causing regression of tumors and retarding progression of the disease. The early data from clinical trials of two new drugs, Femara® and Animidex®, show relapse rates that are lower than those for tamoxifen. These drugs are inhibitors of aromatase, the enzyme needed for the final step in synthesis of estrogens. Finally, two drugs—tamoxifen and Evista® (raloxifene)—are being marketed for breast cancer prevention.

Interestingly, raloxifene blocks estrogen receptors in the breasts and uterus but activates estrogen receptors in bone, providing effective treatment for osteoporosis while possibly decreasing the risk of breast or endometrial (uterine) cancer.

**Ovarian Cancer**

Even though ovarian cancer is the sixth most common form of cancer in females, it is the leading cause of death from all gynecological malignancies (excluding breast cancer) because it is difficult to detect before it metastasizes (spreads) beyond the ovaries. Risk factors associated with ovarian cancer include age (usually over age 50); race (whites are at highest risk); family history of ovarian cancer; more than 40 years of active ovulation; nulliparity or first pregnancy after age 30; a high-fat, low-fiber, vitamin A–deficient diet; and prolonged exposure to asbestos or talc. Early ovarian cancer has no symptoms or only mild ones associated with other common problems, such as abdominal discomfort, heartburn, nausea, loss of appetite, bloating, and flatulence. Later-stage signs and symptoms include an enlarged abdomen, abdominal and/or pelvic pain, persistent gastrointestinal disturbances, urinary complications, menstrual irregularities, and heavy menstrual bleeding.

**Cervical Cancer**

Cervical cancer, carcinoma of the cervix of the uterus, starts with cervical dysplasia (dis-PLÄ-sē-a), a change in the shape, growth, and number of cervical cells. The cells may either return to normal or progress to cancer. In most cases, cervical cancer may be detected in its earliest stages by a Pap test (see page 120). Some evidence links cervical cancer to the virus that causes genital warts, human papillomavirus (HPV). Increased risk is associated with having a large number of sexual partners, having first intercourse at a young age, and smoking cigarettes.

**Vulvovaginal Candidiasis**

*Candida albicans* is a yeastlike fungus that commonly grows on mucous membranes of the gastrointestinal and genitourinary tracts. The organism is responsible for vulvovaginal candidiasis, the most common form of vaginitis (vaj-i-NI-tis), inflammation of the vagina. Candidiasis is characterized by severe itching; a thick, yellow, cheesy discharge; a yeasty odor; and pain. The disorder, experienced at least once by about 75% of females, is usually a result of proliferation of the fungus following antibiotic therapy for another condition. Predisposing conditions include the use of oral contraceptives or cortisone-like medications, pregnancy, and diabetes.

**Sexually Transmitted Diseases**

A sexually transmitted disease (STD) is one that is spread by sexual contact. In most developed countries of the world, such as those of Western Europe, Japan, Australia, and New Zealand, the incidence of STDs has declined markedly during the past 25 years. In the United States, by contrast, STDs have been rising to near-epidemic proportions; they currently affect more than 65 million people. AIDS and hepatitis B, which are sexually transmitted diseases that also may be contracted in other ways, are discussed in Chapters 22 and 24, respectively.

**Chlamydia**

*Chlamydia* (kla-MID-ē-a) is a sexually transmitted disease caused by the bacterium *Chlamydia trachomatis* (chlamy– = cloak). This unusual bacterium cannot reproduce outside body cells; it “cloaks” itself inside cells, where it divides. At present, chlamydia is the most prevalent sexually transmitted disease in the United States. In most cases,
the initial infection is asymptomatic and thus difficult to recognize clinically. In males, urethritis is the principal result, causing a clear discharge, burning on urination, frequent urination, and painful urination. Without treatment, the epididymides may also become inflamed, leading to sterility. In 70% of females with chlamydia, symptoms are absent, but chlamydia is the leading cause of pelvic inflammatory disease. The uterine tubes may also become inflamed, which increases the risk of ectopic pregnancy (implantation of a fertilized ovum outside the uterus) and infertility due to the formation of scar tissue in the tubes.

**Gonorrhea**

Gonorrhea (gon-ô-Rê-a) or “the clap” is caused by the bacterium Neisseria gonorrhoeae. In the United States, 1–2 million new cases of gonorrhea appear each year, most among individuals aged 15–29 years. Discharges from infected mucous membranes are the source of transmission of the bacteria either during sexual contact or during the passage of a newborn through the birth canal. The infection site can be in the mouth and throat after oral-genital contact, in the vagina and penis after genital intercourse, or in the rectum after recto-genital contact.

Males usually experience urethritis with profuse pus drainage and painful urination. The prostate and epididymis may also become infected. In females, infection typically occurs in the vagina, often with a discharge of pus. Both infected males and females may harbor the disease without any symptoms, however, until it has progressed to a more advanced stage; about 5–10% of males and 50% of females are asymptomatic. In females, the infection and consequent inflammation can proceed from the vagina into the uterus, uterine tubes, and pelvic cavity. An estimated 50,000 to 80,000 women in the United States are made infertile by gonorrhea every year as a result of scar tissue formation that closes the uterine tubes. If bacteria in the birth canal are transmitted to the eyes of a newborn, blindness can result. Administration of a 1% silver nitrate solution in the infant’s eyes prevents infection.

**MEDICAL TERMINOLOGY**

**Castration** (kas-TRÄ-shun = to prune) Removal, inactivation, or destruction of the gonads; commonly used in reference to removal of the testes only.

**Colposcopy** (kol-POS-kô-pê; colpo- = vagina; -copy = to view) Visual inspection of the vagina and cervix of the uterus using a colposcope, an instrument that has a magnifying lens (between 5 and 50x) and a light. The procedure generally takes place after an unusual Pap smear.

**Culdoscopy** (kul-DOS-kô-pê; cul- = cul-de-sac; -copy = to examine) A procedure in which a culscope (endoscope) is inserted through the posterior wall of the vagina to view the rectouterine pouch in the pelvic cavity.

**Dysmenorrhea** (dis-men-or-É-a; dys- = difficult or painful) Pain associated with menstruation; the term is usually reserved to describe menstrual symptoms that are severe enough to prevent a woman from functioning normally for one or more days each month. Some cases are caused by uterine tumors, ovarian cysts, pelvic inflammatory disease, or intrauterine devices.

**Dyspareunia** (dis-pa-ROO-nê-a; dys- = difficult; para- = beside; -ene = bed) Pain during sexual intercourse. It may occur in the genital area or in the pelvic cavity, and may be due to inadequate lubrication, inflammation, infection, an improperly fitting diaphragm or cervical cap, endometriosis, pelvic inflammatory disease, pelvic tumors, or weakened uterine ligaments.

**Endocervical curettage** (ënd-ê-kĕr-SID-black; curett = scraper) A procedure in which the cervix is dilated and the endometrium of the uterus is scraped with a spoon-shaped instrument called a curette; commonly called a D and C (dilation and curetage).

**Fibroids** (fi-broids; fibro = fiber; -eidos = resemblance) Noncancerous tumors in the myometrium of the uterus composed of muscular and fibrous tissue. Their growth appears to be related to high levels of estrogens. They do not occur before puberty and usually stop growing after menopause. Symptoms include abnormal menstrual bleeding and pain or pressure in the pelvic area.

**Hermaphroditism** (her-MAF-ro-dit-izm) The presence of both ovarian and testicular tissue in one individual.

**Hypospadias** (hi-pôs-pä-de-as; hypo- = below) A common congenital abnormality in which the urethral opening is displaced. In males, the displaced opening may be on the underside of the penis, at the penoscrotal junction, between the scrotal folds, or in the perineum; in females, the urethra opens into the vagina. The problem can be corrected surgically.
11. At puberty, gonadotropin-releasing hormone (GnRH) stimulates mature sperm consist of a head and a tail. Their function is to fertilize a secondary oocyte.

12. Testosterone controls the growth, development, and maintenance of sex organs; stimulates bone growth, protein anabolism, and sperm maturation; and stimulates development of masculine secondary sex characteristics.

13. Inhibit is produced by Sertoli cells; its inhibition of FSH helps regulate the rate of spermatogenesis.

14. The duct system of the testes includes the seminiferous tubules, straight tubules, and rete testis. Sperm flow out of the testes through the efferent ducts.

15. The ductus epididymis is the site of sperm maturation and storage.

16. The ductus (vas) deferens stores sperm and propels them toward the urethra during ejaculation.

17. Each ejaculatory duct, formed by the union of the duct from the seminal vesicle and ampulla of the ductus (vas) deferens, is the passageway for ejection of sperm and secretions of the seminal vesicles into the first portion of the urethra, the prostatic urethra.

18. The urethra in males is subdivided into three portions: the prostatic, membranous, and spongy (penile) urethra.

19. The seminal vesicles secrete an alkaline, viscous fluid that contains fructose (used by sperm for ATP production). Seminal fluid constitutes about 60% of the volume of semen and contributes to sperm viability.

20. The prostate secretes a slightly acidic fluid that constitutes about 25% of the volume of semen and contributes to sperm motility.

21. The bulbourethral (Cowper's) glands secrete mucus for lubrication and an alkaline substance that neutralizes acid.

22. Semen is a mixture of sperm and seminal fluid; it provides the fluid in which sperm are transported, supplies nutrients, and neutralizes the acidity of the male urethra and the vagina.

23. The penis consists of a root, a body, and a glans penis.

24. Engorgement of the penile blood sinuses under the influence of sexual excitement is called erection.
Milk production is stimulated by prolactin, estrogens, and progesterone.

1. The mammary glands are part of the integumentary system and also are considered part of the reproductive system in females.
2. The mammary glands are modified sweat glands lying superficial to the pectoralis major muscles. Their function is to synthesize, secrete, and store milk.
3. The ovaries, the female gonads, are located in the superior portion of the pelvic cavity, lateral to the uterus.
4. Ovulation is the release of a secondary oocyte into the pelvic cavity. It is brought about by a surge of LH. Signs and symptoms of ovulation include increased basal body temperature; clear, stretchy cervical mucus; changes in the uterine cervix; and abdominal pain.
5. Progesterone works with estrogens to prepare the endometrium for implantation and the mammary glands for milk synthesis.
6. Relaxin relaxes the myometrium at the time of possible implantation. At the end of a pregnancy, relaxin increases the flexibility of the pubic symphysis and helps dilate the uterine cervix to facilitate delivery.
7. During the menstrual phase, the stratum functionalis of the endometrium is shed, discharging blood, tissue fluid, mucus, and epithelial cells.
8. During the preovulatory phase, a group of follicles in the ovaries begins to undergo final maturation. One follicle outgrows the others and becomes dominant while the others degenerate. At the same time, endometrial repair occurs in the uterus. Estrogens are the dominant ovarian hormones during the preovulatory phase.
9. Ovaries produce secondary oocytes, discharge secondary oocytes (the process of ovulation), and secrete estrogens, progesterone, relaxin, and inhibin.
10. The perineum is a diamond-shaped area at the inferior end of the trunk medial to the thighs and buttocks.
11. The uterus is an organ the size and shape of an inverted pear that transports secretions to the vagina and is the normal site of implantation. The endometrium is shed, discharging blood, tissue fluid, mucus, and epithelial cells.
12. The vagina is a passageway for sperm and the menstrual flow, the bladder, and the rectum. Its function is to synthesize, secrete, and eject milk (lactation).
13. Mammary gland development depends on estrogens and progesterone.
14. Milk production is stimulated by prolactin, estrogens, and progesterone; milk ejection is stimulated by oxytocin.

The Female Reproductive Cycle (p. 1112)

1. The function of the ovary is to develop a secondary oocyte; the function of the uterus (menstrual) cycle is to prepare the endometrium each month to receive a fertilized egg. The female reproductive cycle includes both the ovarian and uterine cycles.
2. The ovary is an organ the size and shape of an inverted pear that transports secretions to the vagina and is the normal site of implantation. The endometrium is shed, discharging blood, tissue fluid, mucus, and epithelial cells.
3. The Female Reproductive Cycle (p. 1112)
4. The function of the ovary is to develop a secondary oocyte; the function of the uterus (menstrual) cycle is to prepare the endometrium each month to receive a fertilized egg. The female reproductive cycle includes both the ovarian and uterine cycles.
5. The Female Reproductive Cycle (p. 1112)
6. The ovary is an organ the size and shape of an inverted pear that transports secretions to the vagina and is the normal site of implantation. The endometrium is shed, discharging blood, tissue fluid, mucus, and epithelial cells.
7. The Female Reproductive Cycle (p. 1112)
8. The ovary is an organ the size and shape of an inverted pear that transports secretions to the vagina and is the normal site of implantation. The endometrium is shed, discharging blood, tissue fluid, mucus, and epithelial cells.
9. The Female Reproductive Cycle (p. 1112)
10. The ovary is an organ the size and shape of an inverted pear that transports secretions to the vagina and is the normal site of implantation. The endometrium is shed, discharging blood, tissue fluid, mucus, and epithelial cells.
11. The Female Reproductive Cycle (p. 1112)
12. The ovary is an organ the size and shape of an inverted pear that transports secretions to the vagina and is the normal site of implantation. The endometrium is shed, discharging blood, tissue fluid, mucus, and epithelial cells.
13. The Female Reproductive Cycle (p. 1112)
14. The ovary is an organ the size and shape of an inverted pear that transports secretions to the vagina and is the normal site of implantation. The endometrium is shed, discharging blood, tissue fluid, mucus, and epithelial cells.

Birth Control Methods and Abortion (p. 1117)

1. The gonads develop from intermediate mesoderm. In the presence of the SRY gene, the gonads begin to differentiate into testes during the seventh week. The gonads differentiate into ovaries when the SRY gene is absent.
2. In males, testosterone stimulates development of each mesonephric duct into an epididymis, ductus (vas) deferens, ejaculatory duct, and seminal vesicle, and Müllerian-inhibiting hormone (MIIH) causes the paramesonephric ducts to degenerate. In females, testosterone and MIS are absent; the paramesonephric ducts develop into the uterine tubes, uterus, and vagina and the mesonephric ducts degenerate.
3. The external genitals develop from the genital tubercle and are stimulated to develop into typical male structures by the hormone dihydrotestosterone (DHT). The external genitals develop into female structures when DHT is not produced, the normal situation in female embryos.

Aging and the Reproductive Systems (p. 1122)

1. Puberty is the period when secondary sex characteristics begin to develop and the potential for sexual reproduction is reached.
2. The onset of puberty is marked by pulses or bursts of LH and FSH secretion, each triggered by a pulse of GnRH. The hormone leptin, released by adipose tissue, may signal the hypothalamus that long-term energy stores (triglycerides in adipose tissue) are adequate for reproductive functions to begin.

SELF-QUIZ QUESTIONS

Fill in the blanks in the following statement.
1. The period of time when secondary sexual characteristics begin to develop and the potential for sexual reproduction is reached is called _____. The first menses is called _____, and the permanent cessation of menses is called _____.

Indicate whether the following statements are true or false.
2. Spermatogenesis does not occur at normal core body temperature.
3. The route of sperm from the production in the testes to the exterior of the body is: seminiferous tubules, straight tubules, rete testes, epididymis, ductus (vas) deferens, ejaculatory duct, prostatic urethra, membranous urethra, spongy urethra, external urethral orifice.

Choose the one best answer to the following questions.
4. Which of the following are functions of Sertoli cells? (1) protection of developing spermatogenic cells, (2) nourishment of spermatocytes, spermatids, and sperm, (3) phagocytosis of excess sperm cytoplasm as development proceeds, (4) mediation of the effects of testosterone and FSH, (5) control of movements of spermatogenic cells and release of sperm into the lumen of seminiferous tubules. (a) 1, 2, 4, and 5 (b) 1, 2, 3, and 5 (c) 2, 3, 4, and 5 (d) 1, 2, 3, and 4 (e) 1, 2, 3, 4, and 5

5. Which of the following are true? (1) An erection is a sympathetic response initiated by sexual stimulation. (2) Dilatation of blood vessels supplying erectile tissue results in erection. (3) Nitric oxide causes smooth muscle within erectile tissue to relax, which results in widening of blood sinuses. (4) Ejaculation is a sympathetic reflex coordinated by the sacral region of the spinal cord. (5) The purpose of the corpus cavernosa penis is to keep the spongiosum urethra open during ejaculation. (a) 1, 2, and 3 (b) 1, 2, 3, 4, and 5 (c) 2 and 3 (d) 2, 4, and 5 (e) 1, 2, 3, and 4

6. Which of the following are true concerning estrogens? (1) They promote development and maintenance of female reproductive structures and secondary sex characteristics. (2) They help control fluid and electrolyte balance. (3) They increase protein catabolism. (4) They lower blood cholesterol. (5) In moderate levels, they inhibit the release of GnRH and the secretion of LH and FSH. (a) 1, 2, and 5 (b) 1, 2, 3, and 5 (c) 1, 2, 3, 5 (d) 1, 2, 3, 4 (e) 1, 2, 3, 4, and 5

7. Which of the following statements are correct? (1) A sperm head contains DNA and an acrosome. (2) An acrosome is a specialized lysosome that contains enzymes that enable sperm to produce the ATP needed to propel themselves out of the male reproductive tract. (3) Mitochondria in the midpiece of a sperm produce ATP for sperm motility. (4) A sperm’s tail, a flagellum, propels it along its way. (5) Once ejaculated, sperm are viable and normally are able to fertilize a secondary oocyte for 5 days. (a) 1, 2, 3, and 4 (b) 1, 2, 3, 4, and 5 (c) 1, 3, and 4 (d) 2, 4, and 5 (e) 2, 3, and 4

8. Which of the following statements are correct? (1) Spermatogenesis are stem cells because when they undergo mitosis, some of the daughter cells remain to serve as a reservoir of cells for future mitosis. (2) Meiosis I is a division of pairs of chromosomes resulting in daughter cells with only one member of each chromosome pair. (3) Meiosis II separates the chromatids of each chromosome. (4) Spermiogenesis involves the maturation of spermatids into sperm. (5) The process by which the seminiferous tubules produce haploid sperm is called spermatogenesis. (a) 1, 2, 3, and 5 (b) 1, 2, 3, 4, and 5 (c) 1, 3, and 5 (d) 1, 2, 3, and 4 (e) 1, 3, and 5

9. Which of the following statements are correct? (1) Cells from the yolk sac give rise to oogonia. (2) Ova arise from the germinal epithelium of the ovary. (3) Primary oocytes enter prophase of meiosis I during fetal development but do not complete it until after puberty. (4) Once a secondary oocyte is formed, it proceeds to metaphase of meiosis II and stops at this stage. (5) The secondary oocyte resumes meiosis II and forms the ovum and a polar body only if fertilization occurs. (6) A primary oocyte gives rise to an ovum and four polar bodies. (a) 1, 3, and 5 (b) 1, 3, 4, and 6 (c) 1, 2, 4, and 6 (d) 1, 2, 4, and 5 (e) 1, 2, 5, and 6

10. Which of the following statements are correct? (1) The female reproductive cycle consists of a menstrual phase, a preovulatory phase, ovulation, and a postovulatory phase. (2) During the menstrual phase, small secondary follicles in the ovary begin to enlarge while the uterus is shedding its lining. (3) During the preovulatory phase, a dominant follicle continues to grow and begins to secrete estrogens and inhibin while the uterine lining begins to rebuild.
13. Match the following:

| (a) site of sperm maturation | (1) spermatogenic cells |
| (b) the male copulatory organ; a passageway for ejaculation of sperm and excretion of urine | (2) Sertoli cells |
| (c) sperm-forming cells | (3) Leydig cells |
| (d) produce an alkaline substance that protects sperm by neutralizing acids in the urethra | (4) penis |
| (e) everts sperm into the urethra just before ejaculation | (5) scrotum |
| (f) the supporting structure for the testes | (6) epididymis |
| (g) carries the sperm from the scrotum into the abdominopelvic cavity for release by ejaculation; is cut and tied as a means of sterilization | (7) ductus deferens |
| (h) the shared terminal duct of the reproductive and urinary systems in the male | (8) ejaculatory duct |
| (i) surrounds the urethra at the base of the bladder; produces secretions that contribute to sperm motility and viability | (9) seminal vesicles |
| (j) produce testosterone | (10) seminal vesicles |
| (k) supporting structure that consists of the ductus deferens, testicular artery, autonomic nerves, veins that drain the testes, lymphatic vessels, and cremaster muscle | (11) prostate gland |
| (l) support and protect developing spermatogenic cells; secrete inhibin; form the blood–testis barrier | (12) bulbourethral glands |
| (m) secrete an alkaline fluid to help neutralize acids in the female reproductive tract; secrete fructose for use in ATP production by sperm | (13) urethra |
| (n) contraction and relaxation moves testes near to or away from pelvic cavity | (14) spermatic cord |
| (o) site of spermatogenesis | (15) cremaster muscle |
14. Match the following:

(a) relaxes the uterus by inhibiting myometrial contractions during monthly cycles; increases flexibility of the pubic symphysis during childbirth
(b) stimulates Leydig cells to secrete testosterone in males and triggers ovulation in females
(c) inhibits production of FSH by the anterior pituitary gland
(d) posterior pituitary hormone responsible for uterine contraction and release of milk from mammary glands
(e) stimulates male pattern of development; stimulates protein synthesis; contributes to sex drive
(f) stimulates male external genital development
(g) maintains the corpus luteum during the first trimester of pregnancy
(h) contribute to male sexual behavior, spermatogenesis, and libido
(i) promotes development of female reproductive structures; lowers blood cholesterol
(j) stimulates the initial secretion of estrogens by growing follicles; promotes follicle growth
(k) is secreted by the corpus luteum to maintain the uterine lining during the first trimester of pregnancy
(l) anterior pituitary hormone that stimulates milk production

15. Match the following:

(a) the process during meiosis when portions of homologous chromosomes may be exchanged with each other
(b) refers to cells containing one-half the chromosome number
(c) the cell produced by the union of an egg and a sperm
(d) the degeneration of oogonia before and after birth
(e) a packet of discarded nuclear material from the first or second meiotic division of the egg
(f) refers to cells containing the full chromosome number

CRITICAL THINKING QUESTIONS

1. Twenty-three-year-old Monica and her husband Bill are ready to start a family. They are both avid bicyclists and weight-lifters who carefully watch what they eat and pride themselves on their “buff” bodies. However, Monica is having difficulty becoming pregnant. Monica hasn’t had a menstrual period for some time but informs the doctor that is normal for her. After consulting with her physician, the doctor tells Monica that she needs to cut back on her exercise routine and “put on some weight” in order to get pregnant. Monica is outraged because she figures she will gain enough weight when she is pregnant! Explain to Monica what has happened to her and why weight gain could help her achieve her goal of pregnancy.

2. The term “progesterone” means “for gestation (or pregnancy).” Describe how progesterone helps prepare the female body for pregnancy and helps maintain pregnancy.

3. After having borne five children, Mark’s wife Isabella insists that he have a vasectomy. Mark is afraid that he will “dry up” and won’t be able to perform sexually. How can you reassure him that his reproductive organs will function fine? Will Mark and Isabella be guaranteed that she will not become pregnant immediately after the vasectomy?
CHAPTER 28 • THE REPRODUCTIVE SYSTEMS

28.1 The gonads (testes) produce gametes (sperm) and hormones; the ducts transport, store, and receive gametes; the accessory sex glands secrete materials that support gametes; and the penis assists in the delivery and joining of gametes.

28.2 The cremaster and dartos muscles help regulate the temperature of the testes.

28.3 The tunica vaginalis and tunica albuginea are tissue layers that cover and protect the testes.

28.4 The Leydig (interstitial) cells of the testes secrete testosterone.

28.5 During meiosis I, the number of chromosomes in each cell is reduced by half.

28.6 The sperm head contains the nucleus with 23 highly condensed chromosomes and an acrosome that contains enzymes for penetration of a secondary oocyte; the neck contains centrioles that produce microtubules for the rest of the tail; the midpiece contains mitochondria for ATP production for locomotion and metabolism; the principal and end pieces of the tail provide motility.

28.7 Sertoli cells secrete inhibin.

28.8 Testosterone inhibits secretion of LH, and inhibin inhibits secretion of FSH.

28.9 The seminal vesicles are the accessory sex glands that contribute the largest volume to seminal fluid.

28.10 Two corpora cavernosa penis and one corpus spongiosum penis contain blood sinuses that fill with blood that cannot flow out of the penis as quickly as it flows in. The trapped blood engorges and stiffens the tissue, producing an erection. The corpus spongiosum penis keeps the spongy urethra open so that ejaculation can occur.

28.11 The testes are homologous to the ovaries; the glans penis is homologous to the clitoris; the prostate is homologous to the paraurethral glands; and the bulbourethral glands are homologous to the greater vestibular glands.

28.12 The mesovarium anchors the ovary to the broad ligament of the uterus and the uterine tube; the ovarian ligament anchors it to the uterus; the suspensory ligament anchors it to the pelvic wall.

28.13 Ovarian follicles secrete estrogens; the corpus luteum secretes progesterone, estrogens, relaxin, and inhibin.

28.14 Most ovarian follicles undergo atresia (degeneration).

28.15 Primary oocytes are present in the ovary at birth, so they are as old as the woman. In males, primary spermatocytes are continuously being formed from stem cells (spermatogonia) and thus are only a few days old.

28.16 Fertilization most often occurs in the ampulla of the uterine tube.

28.17 Ciliated columnar epithelial cells and nonciliated (peg) cells with microvilli line the uterine tubes.

28.18 The endometrium is a highly vascularized, secretory epithelium that provides the oxygen and nutrients needed to sustain a fertilized egg; the myometrium is a thick smooth muscle layer that supports the uterine wall during pregnancy and contracts to expel the fetus at birth.

28.19 The stratum basalis of the endometrium provides cells to replace those that are shed (the stratum functionalis) during each menstruation.

28.20 Anterior to the vaginal opening are the mons pubis, clitoris, and prepuce. Lateral to the vaginal opening are the labia minora and labia majora.

28.21 The anterior portion of the perineum is called the urogenital triangle because its borders form a triangle that encloses the urethral (uro-) and vaginal (-genital) orifices.

28.22 Prolactin, estrogens, and progesterone regulate the synthesis of milk. Oxytocin regulates the ejection of milk.

28.23 The principal estrogen is α-estradiol.

28.24 The hormones responsible for the proliferative phase of endometrial growth are estrogens; for ovulation, LH; for growth of the corpus luteum, LH; and for the midcycle surge of LH, estrogens.

28.25 The effect of rising but moderate levels of estrogens is negative feedback inhibition of the secretion of GnRH, LH, and FSH.

28.26 This is negative feedback, because the response is opposite to the stimulus. A reduced amount of negative feedback due to declining levels of estrogens and progesterone stimulates release of GnRH, which in turn increases the production and release of FSH and LH, ultimately stimulating the secretion of estrogens.

28.27 The SRY gene on the Y chromosome is responsible for the development of the gonads into testes.

28.28 The presence of dihydrotestosterone (DHT) stimulates differentiation of the external genitals in males; its absence allows differentiation of the external genitals in females.
DEVELOPMENT, INHERITANCE, AND HOMEOSTASIS

Both the genetic material inherited from parents (heredity) and normal development in the uterus (environment) play important roles in determining the homeostasis of a developing embryo and fetus and the subsequent birth of a healthy child.

Developmental biology is the study of the sequence of events from the fertilization of a secondary oocyte by a sperm cell to the formation of an adult organism. From fertilization through the eighth week of development, a stage called the embryonic period, the developing human is called an embryo (em- = into; -bryo = grow). Embryology (em-bré-OL-øj-ē) is the study of development from the fertilized egg through the eighth week. The fetal period begins at week nine and continues until birth. During this time, the developing human is called a fetus (FÉ-tus = offspring).

Once sperm and a secondary oocyte have developed through meiosis and maturation, and the sperm have been deposited in the vagina, pregnancy can occur. Pregnancy is a sequence of events that begins with fertilization, proceeds to implantation, embryonic development, and fetal development, and normally ends with birth about 38 weeks later, or 40 weeks after the last menstrual period.

Obstetrics (ob-STET-riks; obstetrix = midwife) is the branch of medicine that deals with the management of pregnancy, labor, and the neonatal period, the first 28 days after birth. Prenatal development (prē-NÁ-tal; pre- = before; natal = birth) is the time from fertilization to birth and includes both embryological and fetal development. It is divided into three periods of three calendar months each, called trimesters.

1. The first trimester is the most critical stage of development during which the rudiments of all the major organ systems appear, and also during which the developing organism is the most vulnerable to the effects of drugs, radiation, and microbes.
2. The second trimester is characterized by the nearly complete development of organ systems. By the end of this stage, the fetus assumes distinctively human features.
3. The third trimester represents a period of rapid fetal growth. During the early stages of this period, most of the organ systems are becoming fully functional.

In this chapter, we focus on the developmental sequence from fertilization through implantation, embryonic and fetal development, labor, birth, and the principles of inheritance, the passage of hereditary traits from one generation to another.
**OBJECTIVE**

- Explain the major developmental events that occur during the embryonic period.

**First Week of Development**

The first week of development is characterized by several significant events including fertilization, cleavage of the zygote, blastocyst formation, and implantation.

**Fertilization**

During fertilization (fer-til-i-ZĂ-shun; fertil- = fruitful), the genetic material from a haploid sperm cell (spermatoozoon) and a haploid secondary oocyte merges into a single diploid nucleus. Of the about 200 million sperm introduced into the vagina, fewer than 2 million (1%) reach the cervix of the uterus and only about 200 reach the secondary oocyte. Fertilization normally occurs in the uterine (fallopian) tube within 12 to 24 hours after ovulation. Sperm can remain viable for about 48 hours after deposition in the vagina, although a secondary oocyte is viable for only about 24 hours after ovulation. Thus, pregnancy is most likely to occur if intercourse takes place during a 3-day window—from 2 days before ovulation to 1 day after ovulation.

Sperm swim from the vagina into the cervical canal by the whiplike movements of their tails (flagella). The passage of sperm through the rest of the uterus and then into the uterine tube results mainly from contractions of the walls of these organs. Prostaglandins in semen are believed to stimulate uterine motility at the time of intercourse and to aid in the movement of sperm through the uterus and into the uterine tube. Sperm that reach the vicinity of the oocyte within minutes after ejaculation are not capable of fertilizing it until about seven hours later. During this time in the female reproductive tract, mostly in the uterine tube, sperm undergo capacitation (ka-pas-‘i-TĂ-shun; capac- = capable of), a series of functional changes that cause the sperm’s tail to beat even more vigorously and prepare its plasma membrane to fuse with the oocyte’s plasma membrane. During capacitation, sperm are acted upon by secretions in the female reproductive tract that result in the removal of cholesterol, glycoproteins, and proteins from the plasma membrane around the head of the sperm.

For fertilization to occur, a sperm cell first must penetrate two layers: the corona radiata (kō-RO-na = crown; rā-dē-A-ta = to shine), the granulosa cells that surround the secondary oocyte, and the zona pellucida (ZO-na = zone; pe-LOO-si-da = allowing passage of light), the clear glycoprotein layer between the corona radiata and the oocyte’s plasma membrane (Figure 29.1a). The acrosome, a helmetlike structure that covers the head of a sperm, contains several enzymes (see Figure 28.6 on page 1088). Acrosomal enzymes and strong tail movements by the sperm help it penetrate the cells of the corona radiata and come in contact with the zona pellucida. One of the glycoproteins in the zona pellucida called ZP3 acts as a sperm receptor. Its binding to specific membrane proteins in the sperm head triggers the acrosomal reaction, the release of the contents of the acrosome.

The acrosomal enzymes digest a path through the zona pellucida as the lashing sperm tail pushes the sperm cell onward. Although many sperm bind to ZP3 molecules and undergo acrosomal reactions, only the first sperm cell to penetrate the entire zona pellucida and reach the oocyte’s plasma membrane fuses with the oocyte.

The fusion of a sperm cell with a secondary oocyte sets in motion events that block polyspermy, fertilization by more than one sperm cell. Within a few seconds, the cell membrane of the oocyte depolarizes, which acts as a fast block to polyspermy—a depolarized oocyte cannot fuse with another sperm. Depolarization also triggers the intracellular release of calcium ions, which stimulate exocytosis of secretory vesicles from the oocyte.

**What is capacitation?**

**Figure 29.1 Selected structures and events in fertilization.**

(a) A sperm cell penetrating the corona radiata and zona pellucida around a secondary oocyte. (b) A sperm cell in contact with a secondary oocyte. (c) Male and female pronuclei.
molecules released by exocytosis inactivate ZP3 and harden the entire zona pellucida, events called the slow block to polyspermy.

Once a sperm cell enters a secondary oocyte, the oocyte first must complete meiosis II. It divides into a larger ovum (mature egg) and a smaller second polar body that fragments and disintegrates (see Figure 28.15 on page 1101). The nucleus in the head of the sperm develops into the male pronucleus, and the nucleus of the fertilized ovum develops into the female pronucleus (Figure 29.1c). After the male and female pronuclei form, they fuse, producing a single diploid nucleus that contains 23 chromosomes from each pronucleus. Thus, the fusion of the haploid (n) pronuclei restores the diploid number (2n) of 46 chromosomes. The fertilized ovum now is called a zygote (zygon = yolk).

Dizygotic (fraternal) twins are produced from the independent release of two secondary oocytes and the subsequent fertilization of each by different sperm. They are the same age and in the uterus at the same time, but genetically they are as dissimilar as any other siblings. Dizygotic twins may or may not be the same sex. Because monozygotic (identical) twins develop from a single fertilized ovum, they contain exactly the same genetic material and are always the same sex. Monozygotic twins arise from separation of the developing cells into two embryos, which in 99% of the cases occurs before 8 days have passed. Separations that occur later than 8 days are likely to produce conjoined twins, a situation in which the twins are joined together and share some body structures.

**Cleavage of the Zygote**

After fertilization, rapid mitotic cell divisions of the zygote called cleavage (KLEV-ij) take place (Figure 29.2). The first division of the zygote begins about 24 hours after fertilization and is completed about 6 hours later. Each succeeding division takes slightly less time. By the second day after fertilization, the second cleavage is completed and there are four cells (Figure 29.2b). By the end of the third day, there are 16 cells. The progressively smaller cells produced by cleavage are called blastomeres (BLAS-tō-mérz; blasto- = germ or sprout; -meres = parts). Successive cleavages eventually produce a solid sphere of cells called the morula (MOR-ū-la; morula = mulberry). The morula is still surrounded by the zona pellucida and is about the same size as the original zygote (Figure 29.2c).

**Blastocyst Formation**

By the end of the fourth day, the number of cells in the morula increases as it continues to move through the uterine tube toward the uterine cavity. When the morula enters the uterine cavity on day 4 or 5, a glycogen-rich secretion from the glands of the endometrium of the uterus passes into the uterine cavity and enters the morula through the zona pellucida. This fluid, called uterine milk, along with nutrients stored in the cytoplasm of the blastomeres of the morula, provides nourishment for the developing morula. At the 32-cell stage, the fluid enters the morula, collects between the blastomeres, and reorganizes them around a large fluid-filled cavity called the blastocyst cavity (BLAS-tō-sist; blasto- = germ or sprout; -cyst = bag), also called the blastocoel (Figure 29.2e). Once the blastocyst cavity is formed, the developing mass is called the blastocyst. Though it now has hundreds of cells, the blastocyst is still about the same size as the original zygote.

During the formation of the blastocyst two distinct cell populations arise: the embryoblast and trophoblast (Figure 29.2e). The embryoblast, or inner cell mass, is located internally and eventually develops into the embryo. The trophoblast (TRÖF-ō-blast; tropho- = develop or nourish) is the outer superficial layer of cells that forms the sphere-like wall of the blastocyst. It will ultimately develop into the outer chorionic sac that surrounds the fetus and the fetal portion of the placenta, the site of exchange of nutrients.
and wastes between the mother and fetus. On about the fifth day after fertilization, the blastocyst “hatches” from the zona pellucida by digesting a hole in it with an enzyme, and then squeezing through the hole. This shedding of the zona pellucida is necessary in order to permit the next step, implantation (attachment) into the vascular, glandular endometrial lining of the uterus.

**Implantation**

The blastocyst remains free within the uterine cavity for about 2 days before it attaches to the uterine wall. At this time the endometrium is in its secretory phase. About 6 days after fertilization, the blastocyst loosely attaches to the endometrium in a process called **implantation** (Figure 29.3). As the blastocyst implants, usually in either the posterior portion of the fundus or the body of the uterus, it orients with the inner cell mass toward the body of the uterus, it orients with the inner cell mass toward the

**Figure 29.3** Relation of a blastocyst to the endometrium of the uterus at the time of implantation.

- Implantation, the attachment of a blastocyst to the endometrium, occurs about 6 days after fertilization.

**STUDY QUESTION**

How does the blastocyst merge with and burrow into the endometrium?
endometrium (Figure 29.3b). About seven days after fertilization, the blastocyst attaches to the endometrium more firmly, endometrial glands in the vicinity enlarge, and the endometrium becomes more vascularized (forms new blood vessels). The blastocyst eventually secretes enzymes and burrows into the endometrium and becomes surrounded by it.

Following implantation, the endometrium is known as the decidua (dē-SID-a = falling off). The decidua separates from the endometrium after the fetus is delivered much as it does in normal menstruation. Different regions of the decidua are named based on their positions relative to the site of the implanted blastocyst (Figure 29.4). The decidua basalis is the portion of the endometrium between the embryo and the stratum basalis of the uterus; it provides large amounts of glycogen and lipids for the developing embryo and fetus and later becomes the maternal part of the placenta. The decidua capsularis is the portion of the endometrium located between the embryo and the uterine cavity. The decidua parietalis (par-ri-e-TAL-is) is the remaining modified endometrium that lines the noninvolved areas of the rest of the uterus. As the embryo and later the fetus enlarges, the decidua capsularis bulges into the uterine cavity and fuses with the decidua parietalis, thereby obliterating the uterine cavity. By about 27 weeks, the decidua capsularis degenerates and disappears.

The major events associated with the first week of development are summarized in Figure 29.5.

**Figure 29.4 Regions of the decidua.**

Which part of the decidua helps form the maternal part of the placenta?

**Figure 29.5 Summary of events associated with the first week of development.**

- Fertilization usually occurs in the uterine tube.
- Cleavage (first cleavage completed about 30 hours after fertilization)
- Morula (3–4 days after fertilization)
- Blastocyst (4½–5 days after fertilization)
- Implantation (occurs about 6 days after fertilization)
- Implantation (occurs about 6 days after fertilization)

In which phase of the uterine cycle does implantation occur?
Clinic Connection | Ectopic Pregnancy

Ectopic pregnancy (ek-TOP-ik; ec- = out of; -topic = place) is the development of an embryo or fetus outside the uterine cavity. An ectopic pregnancy usually occurs when movement of the fertilized ovum through the uterine tube is impeded by scar tissue due to a prior infection, decreased movement of the uterine tube smooth muscle, or abnormal tubal anatomy. Although most common sites of ectopic pregnancy is the uterine tube, ectopic pregnancies may also occur in the ovary, abdominal cavity, or uterine cervix. Women who smoke are twice as likely to have an ectopic pregnancy because nicotine in cigarette smoke paralyzes the cilia in the lining of the uterine tube (as does those in the respiratory airways). Scars from pelvic inflammatory disease, previous uterine tube surgery, and previous ectopic pregnancy may also hinder movement of the fertilized ovum.

The signs and symptoms of ectopic pregnancy include one or two missed menstrual cycles followed by bleeding and acute abdominal and pelvic pain. Unless removed, the developing embryo can rupture the uterine tube, often resulting in death of the mother. Treatment options include surgery or the use of a cancer drug called methotrexate, which causes embryonic cells to stop dividing and eventually disappear.

5. When, where, and how does implantation occur?

Second Week of Development

Development of the Trophoblast

About 8 days after fertilization, the trophoblast develops into two layers in the region of contact between the blastocyst and endometrium. These are a syncytiotrophoblast (sin-sı¯-to-TRO¯F-ô-blast) that contains no distinct cell boundaries and a cytotrophoblast (sı¯-to-TRO¯F-ô-blast) between the embryoblast and syncytiotrophoblast that is composed of distinct cells (Figure 29.6a). The two layers of trophoblast become part of the chorion (one of the fetal membranes) as they undergo further growth (see Figure 29.11a inset). During implantation, the syncytiotrophoblast secretes enzymes that enable the blastocyst to penetrate the uterine lining by digesting and liquefying the endometrial cells. Eventually, the blastocyst becomes buried in the endometrium and inner one-third of the myometrium. Another secretion of the trophoblast is human chorionic gonadotropin (hCG), which has actions similar to LH. Human chorionic gonadotropin rescues the corpus luteum from degeneration and sustains its secretion of progesterone and estrogens. These hormones maintain the uterine lining in a secretory state, preventing menstruation. Peak secretion of hCG occurs about the ninth week of pregnancy at the time the placenta is fully developed and produces the progesterone and estrogens that continue to sustain the pregnancy. The presence of hCG in maternal blood or urine is an indicator of pregnancy and is the hormone detected by home pregnancy tests.

Development of the Bilaminar Embryonic Disc

Like those of the trophoblast, cells of the embryoblast also differentiate into two layers around 8 days after fertilization: a hypoblast (primitive endoderm) and epiblast (primitive ectoderm) (Figure 29.6a). Cells of the hypoblast and epiblast together form a flat disc referred to as the bilaminar embryonic disc (bi-LAM-in-ar = two-layered). Soon, a small cavity appears within the epiblast and eventually enlarges to form the amniotic cavity (am-nē-OT-ik; amnio- = lamb).

Development of the Amnion

As the amniotic cavity enlarges, a single layer of squamous cells forms a dome-like roof above the epiblast cells called the amnion (AM-nē-on) (Figure 29.6a). Thus, the amnion forms the roof of the amniotic cavity, and the epiblast forms the floor. Initially, the amnion overlies only the bilaminar embryonic disc. However, as the embryonic disc increases in size and begins to fold, the amnion eventually surrounds the entire embryo (see Figure 29.11a inset), creating the amniotic cavity that becomes filled with amniotic fluid. Most amniotic fluid is initially derived from maternal blood. Later, the fetus contributes to the fluid by excreting urine into the amniotic cavity. Amniotic fluid serves as a shock absorber for the fetus, helps regulate fetal body temperature, helps prevent the fetus from drying out, and prevents adhesions between the skin of the fetus and surrounding tissues. The amnion usually ruptures just before birth; it and its fluid constitute the “bag of waters.” Embryonic cells are normally sloughed off into amniotic fluid. They can be examined in a procedure called amniocentesis, which involves withdrawing some of the amniotic fluid that bathes the developing fetus and analyzing the fetal cells and dissolved substances (see page 1154).

Development of the Yolk Sac

Also on the eighth day after fertilization, cells at the edge of the hypoblast migrate and cover the inner surface of the blastocyst wall (Figure 29.6a). The migrating columnar cells become squamous (flat) and then form a thin membrane referred to as the exocoelomic membrane (ek’-so-ē-LO-mik; exo- = outside; -koilos = space). Together with the hypoblast, the exocoelomic membrane forms the wall of the yolk sac, the former blastocyst cavity during earlier development (Figure 29.6b). As a result, the bilaminar embryonic disc is now positioned between the amniotic cavity and yolk sac.

Since human embryos receive their nutrients from the endometrium, the yolk sac is relatively empty, small, and decreases in size as development progresses (see Figure 29.11a inset). Nevertheless, the yolk sac has several important functions in humans: supplies nutrients to the embryo during the second and third weeks of development; is the source of blood cells from the third through sixth weeks; contains the first cells (primordial germ cells) that will eventually migrate into the developing gonads, differentiate into the primitive germ cells, and form...
Figure 29.6 Principal events of the second week of development.

About 8 days after fertilization, the trophoblast develops into a syncytiotrophoblast and a cytotrophoblast; the inner cell mass develops into a hypoblast and epiblast (bilaminar embryonic disc).

How is the bilaminar embryonic disc connected to the trophoblast?
Development of Sinusoids

On the ninth day after fertilization, the blastocyst becomes completely embedded in the endometrium. As the syncytiotrophoblast expands, small spaces called lacunae (la-KOÖ-nē = little lakes) develop within it (Figure 29.6b). By the twelfth day of development, the lacunae fuse to form larger, interconnecting spaces called lacunar networks (Figure 29.6c). Endometrial capillaries around the developing embryo become dilated and are referred to as maternal sinusoids. As the syncytiotrophoblast erodes some of the maternal sinusoids and endometrial glands, maternal blood and secretions from the glands enter the lacunar networks and flow through them. Maternal blood is both a rich source of materials for embryonic nutrition and a disposal site for the embryo’s wastes.

Development of the Extraembryonic Coelom

About the twelfth day after fertilization, the extraembryonic mesoderm develops. These mesodermal cells are derived from the yolk sac and form a connective tissue layer (mesenchyme) around the amnion and yolk sac (Figure 29.6c). Soon a number of large cavities develop in the extraembryonic mesoderm, which then fuse to form a single, larger cavity called the extraembryonic coelom (SE-lōm).

Development of the Chorion

The extraembryonic mesoderm, together with the two layers of the trophoblast (the cytotrophoblast and syncytiotrophoblast), together form the chorion (KOR-ē-on = membrane) (Figure 29.6c). The chorion surrounds the embryo and, later, the fetus (see Figure 29.11a inset). Eventually it becomes the principal embryonic part of the placenta, the structure for exchange of materials between mother and fetus. The chorion also protects the embryo and fetus from the immune responses of the mother in two ways: (1) It secretes proteins that block antibody production by the mother. (2) It promotes the production of T lymphocytes that suppress the normal immune response in the uterus. Finally, the chorion produces human chorionic gonadotropin (hCG), an important hormone of pregnancy (see Figure 29.16).

The inner layer of the chorion eventually fuses with the amnion. With the development of the chorion, the extraembryonic coelom is now referred to as the chorionic cavity. By the end of the second week of development, the bilaminar embryonic disc becomes connected to the trophoblast by a band of extraembryonic mesoderm called the connecting (body) stalk (see Figure 29.7, inset). The connecting stalk is the future umbilical cord.

**CHECKPOINT**

7. How is the bilaminar embryonic disc formed?
8. Describe the formation of the amnion, yolk sac, and chorion and explain their functions.
9. Why are sinusoids important during embryonic development?

**Third Week of Development**

The third embryonic week begins a six-week period of very rapid development and differentiation. During the third week, the three primary germ layers are established and lay the groundwork for organ development in weeks four through eight.

**Gastrulation**

The first major event of the third week of development, gastrulation (gas’-troo-LĀ-shun), occurs about 15 days after fertilization. In this process, the bilaminar (two-layered) embryonic disc, consisting of epiblast and hypoblast, transforms into a trilaminar (three-layered) embryonic disc consisting of three primary germ layers: the ectoderm, mesoderm, and endoderm. The primary germ layers are the major embryonic tissues from which the various tissues and organs of the body develop.

Gastrulation involves the rearrangement and migration of cells from the epiblast. The first evidence of gastrulation is the formation of the primitive streak, a faint groove on the dorsal surface of the epiblast that elongates from the posterior to the anterior part of the embryo (Figure 29.7a). The primitive streak clearly establishes the head and tail ends of the embryo, as well as its right and left sides. At the head end of the primitive streak a small group of epiblastic cells forms a rounded structure called the primitive node.

Following formation of the primitive streak, cells of the epiblast move inward below the primitive streak and detach from the epiblast (Figure 29.7b) in a process called invagination (in-vaj-i-NA-shun). Once the cells have invaginated, some of them displace the hypoblast, forming the endoderm (endo- = inside; -derm = skin). Other cells remain between the epiblast and newly formed endoderm to form the mesoderm (meso- = middle). Cells remaining in the epiblast then form the ectoderm (ecto- = outside). The ectoderm and endoderm are epithelia composed of tightly packed cells; the mesoderm is a loosely organized connective tissue (mesenchyme). As the embryo develops, the endoderm ultimately becomes the epithelial lining of the gastrointestinal tract, respiratory tract, and several other organs. The mesoderm gives rise to muscles, bones, and other connective tissues, and the peritoneum. The ectoderm develops into the epidermis of the skin and the nervous system. Table 29.1 on page 1142 provides more details about the fates of these primary germ layers.

About 16 days after fertilization, mesodermal cells from the primitive node migrate toward the head end of the embryo and form a hollow tube of cells in the midline called the notochordal process (nō-to-KOR-dal) (Figure 29.8 on page 1142). By days 22–24, the notochordal process becomes a solid cylinder of cells called the notochord (nō-to-KORD; noto- = back; -chord = cord). This structure plays an extremely important role in induction (in-DUK-shun), the process by which one tissue (inducing tissue) stimulates the development of an adjacent unspecialized tissue (responding tissue) into a specialized one. An inducing tissue usually produces a chemical substance that influences the responding tissue. The notochord induces certain mesodermal cells to develop

into the vertebral bodies. It also forms the nucleus pulposus of the intervertebral discs (see Figure 7.24 on page 229).

Also during the third week of development, two faint depressions appear on the dorsal surface of the embryo. The structure closer to the head end is called the oropharyngeal membrane (or-oh-fa-RIN-jé-al; oro- = mouth; -pharyngeal = pertaining to the pharynx) (Figure 29.8a, b). It breaks down during the fourth week to connect the mouth cavity to the pharynx and the remainder of the gastrointestinal tract. The structure closer to the tail end is called the cloacal membrane (klo-A-kul = sewer), which degenerates in the seventh week to form the openings of the anus and urinary and reproductive tracts.

When the cloacal membrane appears, the wall of the yolk sac forms a small vascularized outpouching called the allantois (a-LAN-to-is; allant- = sausage) that extends into the connecting stalk (Figure 29.8b). In most other mammals, the allantois is used for gas exchange and waste removal. Because of the role of the human placenta in these activities, the allantois is not a

Figure 29.8 Development of the notochordal process.

The notochordal process develops from the primitive node and later becomes the notochord.

What is the significance of the notochord?
prominent structure in humans (see Figure 29.11a, inset). Nevertheless, it does function in the early formation of blood and blood vessels, and it is associated with the development of the urinary bladder.

**Neurulation**

In addition to inducing mesodermal cells to develop into vertebral bodies, the notochord also induces ectodermal cells over it to form the **neural plate** (Figure 29.9a). (Also see Figure 14.27 on page 537.) By the end of the third week, the lateral edges of the neural plate become more elevated and form the **neural fold** (Figure 29.9b). The depressed midregion is called the **neural groove** (Figure 29.9c). Generally, the neural folds approach each other and fuse, thus converting the neural plate into a **neural tube** (Figure 29.9d). This occurs first near the middle of the embryo and then progresses toward the head and tail ends. Neural

Which structures develop from the neural tube and somites?
tube cells then develop into the brain and spinal cord. The process by which the neural plate, neural folds, and neural tube form is called neurulation (noor-oo-LA-shun).

As the neural tube forms, some of the ectodermal cells from the tube migrate to form several layers of cells called the neural crest (see Figure 14.27b on page 537). Neural crest cells give rise to spinal and cranial nerves and their ganglia, autonomic nervous system ganglia, the meninges of the brain and spinal cord, the adrenal medullae, and several skeletal and muscular components of the head.

At about four weeks after fertilization, the head end of the neural tube develops into three enlarged areas called primary brain vesicles (see Figure 14.28 on page 538): the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain). At about five weeks, the prosencephalon develops into secondary brain vesicles called the telencephalon and diencephalon, and the rhombencephalon develops into secondary brain vesicles called the metencephalon and myelencephalon. The areas of the neural tube adjacent to the myelencephalon develop into the spinal cord. The parts of the brain that develop from the various brain vesicles are described on page 496 in Chapter 14.

---

**Development of Somites**

By about the 17th day after fertilization, the mesoderm adjacent to the notochord and neural tube forms paired longitudinal columns of paraxial mesoderm (par-AK-sè-al; para- = near) (Figure 29.9b). The mesoderm lateral to the paraxial mesoderm forms paired cylindrical masses called intermediate mesoderm. The mesoderm lateral to the intermediate mesoderm consists of a pair of flattened sheets called lateral plate mesoderm. The paraxial mesoderm soon segments into a series of paired, cube-shaped structures called somites (SÔ-mîts = little bodies). By the end of the fifth week, 42–44 pairs of somites are present. The number of somites that develop over a given period can be correlated to the approximate age of the embryo.

Each somite differentiates into three regions: a myotome, a dermatome, and a sclerotome (see Figure 10.19b on page 329). The myotomes develop into the skeletal muscles of the neck, trunk, and limbs; the dermatomes form connective tissue, including the dermis of the skin; and the sclerotomes give rise to the vertebral and ribs.

---

**Development of the Intraembryonic Coelom**

In the third week of development, small spaces appear in the lateral plate mesoderm. These spaces soon merge to form a larger cavity called the intraembryonic coelom (SÈ-lom = cavity). This cavity splits the lateral plate mesoderm into two parts called the splanchnic mesoderm and somatic mesoderm (Figure 29.9d).

Splanchnic mesoderm (SPLANGK-nik = visceral) forms the heart and the visceral layer of the serous pericardium, blood vessels, the smooth muscle and connective tissues of the respiratory and digestive organs, and the visceral layer of the serous membrane of the pleurae and peritoneum. Somatic mesoderm (sô-MAT-ik; soma- = body) gives rise to the bones, ligaments, and dermis of the limbs and the parietal layer of the serous membrane of the pericardium, pleurae, and peritoneum.

---

**Development of the Cardiovascular System**

At the beginning of the third week, angiogenesis (an-jë-Ö-JEN-e-sis; angio- = vessel; -genesis = production), the formation of blood vessels, begins in the extraembryonic mesoderm in the yolk sac, connecting stalk, and chorion. This early development is necessary because there is insufficient yolk in the yolk sac and ovum to provide adequate nutrition for the rapidly developing embryo. Angiogenesis is initiated when mesodermal cells differentiate into hemangioblasts. These then develop into cells called angioblasts, which aggregate to form isolated masses of cells referred to as blood islands (see Figure 21.31 on page 823). Spaces soon develop in the blood islands and form the lumens of blood vessels. Some angioblasts arrange themselves around each space to form the endothelium and the tunics (layers) of the developing blood vessels. As the blood islands grow and fuse, they then form an extensive system of blood vessels throughout the embryo.

About 3 weeks after fertilization, blood cells and blood plasma begin to develop outside the embryo from hemangioblasts in the blood vessels in the walls of the yolk sac, allantois, and chorion. These then develop into pluripotent stem cells that form blood cells. Blood formation begins within the embryo at about the fifth week in the liver and the twelfth week in the spleen, red bone marrow, and thymus.

The heart forms from splanchnic mesoderm in the head end of the embryo on days 18 and 19. This region of mesodermal cells is called the cardiogenic area (kar-dë-Ö-JEN-ik; cardio- = heart; -genic = producing). In response to induction signals from the underlying endoderm, these mesodermal cells form a pair of endocardial tubes (see Figure 20.19 on page 748). The tubes then fuse to form a single primitive heart tube. By the end of the third week, the primitive heart tube bends on itself, becomes S-shaped, and begins to beat. It then joins blood vessels in other parts of the embryo, connecting stalk, chorion, and yolk sac to form a primitive cardiovascular system.

---

**Development of the Chorionic Villi and Placenta**

As the embryonic tissue invades the uterine wall, maternal uterine vessels are eroded and maternal blood fills spaces, called
lacunae, within the invading tissue. By the end of the second week of development, chorionic villi (ko-re-ON-ik VIL-i) begin to develop. These fingerlike projections consist of chorion (syncytiotrophoblast surrounded by cytotrophoblast) that projects into the endometrial wall of the uterus (Figure 29.10a). By the end of the third week, blood capillaries develop in the chorionic villi (Figure 29.10b). Blood vessels in the chorionic villi connect to the embryonic heart by way of the umbilical arteries and umbilical vein through the connecting (body) stalk, which will eventually become the umbilical cord (Figure 29.10c). The fetal blood capillaries within the chorionic villi project into the lacunae, which unite to form the intervillosous spaces that bathe the chorionic villi with maternal blood. As a result, maternal and fetal blood vessels are in close proximity. Note, however, that maternal and fetal blood vessels do not join, and the blood they carry does not normally mix. Instead, oxygen and nutrients in the blood of the mother’s intervillous spaces, which are the spaces between chorionic villi, diffuse across the cell membranes into the capillaries of the villi. Waste products such as carbon dioxide diffuse in the opposite direction.

**Figure 29.10 Development of chorionic villi.**

Blood vessels in chorionic villi connect to the embryonic heart via the umbilical arteries and umbilical vein.

(a) Frontal section through uterus showing blastocyst, about 13 days after fertilization

(b) Details of two chorionic villi, about 21 days after fertilization

(c) Frontal section through uterus showing an embryo and its vascular supply, about 21 days after fertilization

Why is development of chorionic villi important?
Placentation (plas'-en-TĀ-shun) is the process of forming the placenta (pla-SEN-ta = flat cake), the site of exchange of nutrients and wastes between the mother and fetus. The placenta also produces hormones needed to sustain the pregnancy (see Figure 29.16). The placenta is unique because it develops from two separate individuals, the mother and the fetus.

By the beginning of the twelfth week, the placenta has two distinct parts: (1) the fetal portion formed by the chorionic villi of the chorion and (2) the maternal portion formed by the decidua basalis of the endometrium (Figure 29.11a). When fully developed, the placenta is shaped like a pancake (Figure 29.11b). Functionally, the placenta allows oxygen and nutrients to diffuse from maternal blood into fetal blood while carbon dioxide and wastes diffuse from fetal blood into maternal blood. The placenta also is a protective barrier because most microorganisms cannot pass through it. However, certain viruses, such as those that cause AIDS, German measles, chickenpox, measles, encephalitis, and poliomyelitis, can cross the placenta. Many drugs, alcohol, and some substances that can cause birth defects also pass freely. The placenta stores nutrients such as carbohydrates, proteins, calcium, and iron, which are released into fetal circulation as required.

The actual connection between the placenta and embryo, and later the fetus, is through the umbilical cord (um-BIL-i-kul = navel), which develops from the connecting stalk and is usually about 2 cm (1 in.) wide and about 50–60 cm (20–24 in.) in length.
length. The umbilical cord consists of two umbilical arteries that carry deoxygenated fetal blood to the placenta, one umbilical vein that carries oxygen and nutrients acquired from the mother’s intervillous spaces into the fetus, and supporting mucous connective tissue called Wharton’s jelly derived from the allantois. A layer of amnion surrounds the entire umbilical cord and gives it a shiny appearance (Figure 29.11a). In some cases, the umbilical vein is used to transfuse blood into a fetus or to introduce drugs for various medical treatments.

In about 1 in 200 newborns, only one of the two umbilical arteries is present in the umbilical cord. It may be due to failure of the artery to develop or degeneration of the vessel early in development. Nearly 20% of infants with this condition develop cardiovascular defects.

After the birth of the baby, the placenta detaches from the uterus and is therefore termed the afterbirth. At this time, the umbilical cord is tied off and then severed. The small portion (about an inch) of the cord that remains attached to the infant begins to wither and falls off, usually within 12 to 15 days after birth. The area where the cord was attached becomes covered by a thin layer of skin, and scar tissue forms. The scar is the umbilicus (navel).

Pharmaceutical companies use human placentas as a source of hormones, drugs, and blood; portions of placentas are also used for burn coverage. The placental and umbilical cord veins can also be used in blood vessel grafts, and cord blood can be frozen to provide a future source of pluripotent stem cells, for example, to repopulate red bone marrow following radiotherapy for cancer.

**CLINICAL CONNECTION Placenta Previa**

In some cases, the entire placenta or part of it may become implanted in the inferior portion of the uterus, near or covering the internal os of the cervix. This condition is called placenta previa (PRE-vé-a = before or in front of). Although placenta previa may lead to spontaneous abortion, it also occurs in approximately 1 in 250 live births. It is dangerous to the fetus because it may cause premature birth and intrauterine hypoxia due to maternal bleeding. Maternal mortality is increased due to hemorrhage and infection. The most important symptom is sudden, painless, bright-red vaginal bleeding in the third trimester. Cesarean section is the preferred method of delivery in placenta previa.

**Fourth Week of Development**

The fourth through eighth weeks of development are very significant in embryonic development because all major organs appear during this time. The term organogenesis (or’-ga-nó-JEN-e-sis) refers to the formation of body organs and systems. By the end of the eighth week, all the major body systems have begun to develop, although their functions for the most part are minimal. Organogenesis requires the presence of blood vessels to supply developing organs with oxygen and other nutrients. However, recent studies suggest that blood vessels play a significant role in organogenesis even before blood begins to flow within them. The endothelial cells of blood vessels apparently provide some type of developmental signal, either a secreted substance or a direct cell-to-cell interaction, that is necessary for organogenesis.

During the fourth week after fertilization, the embryo undergoes very dramatic changes in shape and size, nearly tripling its size. It is essentially converted from a flat, two-dimensional trilaminar embryonic disk to a three-dimensional cylinder, a process called embryonic folding (Figure 29.12a–d). The cylinder consists of endoderm in the center (gut), ectoderm on the outside (epidermis), and mesoderm in between. The main force responsible for embryonic folding is the different rates of growth of various parts of the embryo, especially the rapid longitudinal growth of the nervous system (neural tube). Folding in the median plane produces a head fold and a tail fold; folding in the horizontal plane results in the two lateral folds. Overall, due to the foldings, the embryo curves into a C-shape.

The head fold brings the developing heart and mouth into their eventual adult positions. The tail fold brings the developing anus into its eventual adult position. The lateral folds form as the lateral margins of the trilaminar embryonic disc bend ventrally. As they move toward the midline, the lateral folds incorporate the dorsal part of the yolk sac into the embryo as the primitive gut, the forerunner of the gastrointestinal tract (Figure 29.12b). The primitive gut differentiates into an anterior foregut, an intermediate midgut, and a posterior hindgut (Figure 29.12c). The fates of the foregut, midgut, and hindgut are described on page 967. Recall that the oropharyngeal membrane is located in the head end of the embryo (see Figure 29.8). It separates the future pharyngeal (throat) region of the foregut from the stomodeum (sto-mó-DÉ-um; stomo- = mouth), the future oral cavity. Because of head folding, the oropharyngeal membrane moves downward and the foregut and stomodeum move closer to their final positions. When the oropharyngeal membrane ruptures during the fourth week, the pharyngeal region of the pharynx is brought into contact with the stomodeum.

In a developing embryo, the last part of the hindgut expands into a cavity called the cloaca (see Figure 26.23 on page 1054). On the outside of the embryo is a small cavity in the tail region called the proctodeum (prok-tó-DÉ-um; procto- = anus) (Figure 29.12c). Separating the cloaca from the proctodeum is the cloacal membrane (see Figure 29.8). During embryonic development, the cloaca divides into a ventral urogenital sinus and a dorsal anorectal canal. As a result of tail folding, the cloacal
Figure 29.12 Embryonic folding.

Embryonic folding converts the two-dimensional trilaminar embryonic disc into a three-dimensional cylinder.

What are the results of embryonic folding?
membrane moves downward and the urogenital sinus, anorectal canal, and proctodeum move closer to their final positions. When the cloacal membrane ruptures during the seventh week of development, the urogenital and anal openings are created.

Along with embryonic folding, development of somites and the neural tube (previously described) occurs during the fourth week of development. In addition, several pharyngeal (branchial) arches develop on each side of the future head and neck regions (Figure 29.13). These five paired structures form swellings on the surface of the embryo beginning on the 22nd day after fertilization. Each pharyngeal arch consists of an outer covering of ectoderm, an inner covering of endoderm, and mesoderm in between. The pharyngeal arches also contain an artery, a cranial nerve, cartilage, and muscular tissue. Also on the outside of the embryo are a series of grooves between the pharyngeal arches called pharyngeal clefts, which separate the pharyngeal arches (Figure 29.13a). Simultaneous with the development of the pharyngeal arches and clefts, four distinct pairs of pharyngeal pouches develop inside the embryo (Figure 29.13b).

**Figure 29.13** Development of pharyngeal arches, pharyngeal clefts, and pharyngeal pouches.

The pharyngeal pouches are endoderm-lined, balloon-like outgrowths of the primitive pharynx, the most cranial part of the foregut.

Just as the somite gives rise to specified structures in the body wall, each pharyngeal arch, cleft, and pouch gives rise to specified structures in the head and neck. Each pharyngeal arch is a developmental unit and includes a skeletal component, muscle, nerve, and blood vessels. In the human embryo, there are four obvious pharyngeal arches and two less distinct arches. Each of these arches develops into a specific and unique component of the head and neck region. For example, the first pharyngeal arch is often called the mandibular arch because it forms the jaws (the mandible is the lower jawbone).

The first sign of a developing ear is a thickened area of ectoderm, the otic placode (future internal ear), which can be distinguished about 22 days after fertilization (see Figure 29.13a). A thickened area of ectoderm called the lens placode (see Figure 29.13a), which will become the eye, also appears at this time.

By the middle of the fourth week, the upper limbs begin their development as outgrowths of mesoderm covered by ectoderm called upper limb buds (see Figure 8.18b on page 259). By the end of the fourth week, the lower limb buds develop. The heart also forms a distinct projection on the ventral surface of the embryo called the heart prominence (see Figure 8.18a). At the end of the fourth week the embryo has a distinctive tail (see Figure 8.18b).

**Fifth Through Eighth Weeks of Development**

During the fifth week of development, there is a very rapid development of the brain, so growth of the head is considerable. By the end of the sixth week, the head grows even larger relative to the trunk, and the limbs show substantial development (see Figure 8.18c on page 259). In addition, the neck and trunk begin to straighten, and the heart is now four-chambered. By the seventh week, the various regions of the limbs become distinct and the beginnings of digits appear (see Figure 8.18d). At the start of the eighth week (the final week of the embryonic period), the digits of the hands are short and webbed, the tail is shorter but still visible, the eyes are open, and the auricles of the ears are visible (see Figure 8.18c). By the end of the eighth week, all regions of limbs are apparent; the digits are distinct and no longer webbed due to removal of cells via apoptosis. Also, the eyelids come together and may fuse, the tail disappears, and the external genitals begin to differentiate. The embryo now has clearly human characteristics.

**CHECKPOINT**

17. How does embryonic folding occur?
18. How does the primitive gut form, and what is its significance?
19. What is the origin of the structures of the head and neck?
20. What are limb buds?
21. What changes occur in the limbs during the second half of the embryonic period?
FETAL PERIOD

OBJECTIVE
• Describe the major events of the fetal period.

During the fetal period, tissues and organs that developed during the embryonic period grow and differentiate. Very few new structures appear during the fetal period, but the rate of body growth is remarkable, especially during the second half of intrauterine life. For example, during the last two and one-half
months of intrauterine life, half of the full-term weight is added. At the beginning of the fetal period, the head is half the length of the body. By the end of the fetal period, the head size is only one-quarter the length of the body. During the same period, the limbs also increase in size from one-eighth to one-half the fetal length. The fetus is also less vulnerable to the damaging effects of drugs, radiation, and microbes than it was as an embryo.

A summary of the major developmental events of the embryonic and fetal periods is presented in Table 29.2 and illustrated in Figure 29.14 on page 1152.

### TABLE 29.2

Summary of Changes During Embryonic and Fetal Development

<table>
<thead>

<tbody>
<tr>
<td><strong>EMBRYONIC PERIOD</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>1–4 weeks</td>
<td>0.6 cm (3/16 in.)</td>
<td>Primary germ layers and notochord develop. Neurulation occurs. Primary brain vesicles, somites, and intraembryonic coelom develop. Blood vessel formation begins and blood forms in yolk sac, allantois, and chorion. Heart forms and begins to beat. Chorionic villi develop and placental formation begins. The embryo folds. The primitive gut, pharyngeal arches, and limb buds develop. Eyes and ears begin to develop, tail forms, and body systems begin to form.</td>
</tr>
<tr>
<td>5–8 weeks</td>
<td>3 cm (1.25 in.) 1 g (1/30 oz)</td>
<td>Limbs become distinct and digits appear. Heart becomes four-chambered. Eyes are far apart and eyelids are fused. Nose develops and is flat. Face is more humanlike. Bone formation begins. Blood cells start to form in liver. External genitals begin to differentiate. Tail disappears. Major blood vessels form. Many internal organs continue to develop.</td>
</tr>
<tr>
<td><strong>FETAL PERIOD</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>9–12 weeks</td>
<td>7.5 cm (3 in.) 30 g (1 oz)</td>
<td>Head constitutes about half the length of the fetal body, and fetal length nearly doubles. Brain continues to enlarge. Face is broad, with eyes fully developed, closed, and widely separated. Nose develops a bridge. External ears develop and are low set. Bone formation continues. Upper limbs almost reach final relative length but lower limbs are not quite as well developed. Heartbeat can be detected. Gender is distinguishable from external genitals. Urine secreted by fetus is added to amniotic fluid. Red bone marrow, thymus, and spleen participate in blood cell formation. Fetus begins to move, but its movements cannot be felt yet by the mother. Body systems continue to develop.</td>
</tr>
<tr>
<td>13–16 weeks</td>
<td>18 cm (6.5–7 in.) 100 g (4 oz)</td>
<td>Head is relatively smaller than rest of body. Eyes move medially to their final positions, and ears move to their final positions on the sides of the head. Lower limbs lengthen. Fetus appears even more humanlike. Rapid development of body systems occurs.</td>
</tr>
<tr>
<td>17–20 weeks</td>
<td>25–30 cm (10–12 in.) 200–450 g (0.5–1 lb)</td>
<td>Head is more proportionate to rest of body. Eyebrows and head hair are visible. Growth slows but lower limbs continue to lengthen. Vernix caseosa (fatty secretions of oil glands and dead epithelial cells) and lanugo (delicate fetal hair) cover fetus. Brown fat forms and is the site of heat production. Fetal movements are commonly felt by mother (quickening).</td>
</tr>
<tr>
<td>21–25 weeks</td>
<td>27–35 cm (11–14 in.) 550–800 g (1.25–1.5 lb)</td>
<td>Head becomes even more proportionate to rest of body. Weight gain is substantial, and skin is pink and wrinkled.</td>
</tr>
<tr>
<td>26–29 weeks</td>
<td>32–42 cm (13–17 in.) 110–1350 g (2.5–3 lb)</td>
<td>Head and body are more proportionate and eyes are open. Toenails are visible. Body fat is 3.5% of total body mass and additional subcutaneous fat smooths out some wrinkles. Testes begin to descend toward scrotum at 28 to 32 weeks. Red bone marrow is major site of blood cell production. Many fetuses born prematurely during this period survive if given intensive care because lungs can provide adequate ventilation and central nervous system is developed enough to control breathing and body temperature.</td>
</tr>
<tr>
<td>30–34 weeks</td>
<td>41–45 cm (16.5–18 in.) 2000–2300 g (4.5–5 lb)</td>
<td>Skin is pink and smooth. Fetus assumes upside-down position. Body fat is 8% of total body mass. Fetuses 33 weeks and older usually survive if born prematurely.</td>
</tr>
<tr>
<td>35–38 weeks</td>
<td>50 cm (20 in.) 3200–3400 g (7–7.5 lb)</td>
<td>By 38 weeks circumference of fetal abdomen is greater than that of head. Skin is usually bluish-pink, and growth slows as birth approaches. Body fat is 16% of total body mass. Testes are usually in scrotum in full-term male infants. Even after birth, an infant is not completely developed; an additional year is required, especially for complete development of the nervous system.</td>

How does mid-fetal weight compare to end-fetal weight?
TERATOGENS

OBJECTIVE

- Define a teratogen and list several examples of teratogens.

Exposure of a developing embryo or fetus to certain environmental factors can damage the developing organism or even cause death. A teratogen (TER-a-to-jen; terato- = monster; -gen = creating) is any agent or influence that causes developmental defects in the embryo. In the following sections we briefly discuss several examples.

Chemicals and Drugs

Because the placenta is not an absolute barrier between the maternal and fetal circulations, any drug or chemical that is dangerous to an infant should be considered potentially dangerous to the fetus when given to the mother. Alcohol is by far the number-one fetal teratogen. Intrauterine exposure to even a small amount of alcohol may result in fetal alcohol syndrome (FAS), one of the most common causes of mental retardation and the most common preventable cause of birth defects in the United States. The symptoms of FAS may include slow growth before and after birth, characteristic facial features (short palpebral fissures, a thin upper lip, and sunken nasal bridge), defective heart and other organs, malformed limbs, genital abnormalities, and central nervous system damage. Behavioral problems, such as hyperactivity, extreme nervousness, reduced ability to concentrate, and an inability to appreciate cause-and-effect relationships, are common.

Other teratogens include certain viruses (hepatitis B and C and certain papilloma viruses that cause sexually transmitted diseases); pesticides; defoliants (chemicals that cause plants to shed their leaves prematurely); industrial chemicals; some hormones; antibiotics; oral anticoagulants, anticonvulsants, anti-tumor agents, thyroid drugs, thalidomide, diethylstilbestrol (DES), and numerous other prescription drugs; LSD; and cocaine. A pregnant woman who uses cocaine, for example, subjects the fetus to higher risk of retarded growth, attention and orientation problems, hyperirritability, a tendency to stop breathing, malformed or missing organs, strokes, and seizures. The risks of spontaneous abortion, premature birth, and stillbirth also increase with fetal exposure to cocaine.

Cigarette Smoking

Strong evidence implicates cigarette smoking during pregnancy as a cause of low infant birth weight; there is also a strong association between smoking and a higher fetal and infant mortality rate. Women who smoke have a much higher risk of an ectopic pregnancy. Cigarette smoke may be teratogenic and may cause cardiac abnormalities as well as anencephaly (see page 1144). Maternal smoking also is a significant factor in the development of cleft lip and palate and has been linked with sudden infant death syndrome (SIDS). Infants nursing from smoking mothers have also been found to have an increased incidence of gastrointestinal disturbances. Even a mother’s exposure to secondhand cigarette smoke (breathing air containing tobacco smoke) during pregnancy or while nursing predisposes her baby to increased incidence of respiratory problems, including bronchitis and pneumonia, during the first year of life.

Irradiation

Ionizing radiation of various kinds is a potent teratogen. Exposure of pregnant mothers to x-rays or radioactive isotopes during the embryo’s susceptible period of development may cause microcephaly (small head size relative to the rest of the body), mental retardation, and skeletal malformations. Caution is advised, especially during the first trimester of pregnancy.

CHECKPOINT

24. What are some of the symptoms of fetal alcohol syndrome?
25. How does cigarette smoking affect embryonic and fetal development?

PRENATAL DIAGNOSTIC TESTS

OBJECTIVE

- Describe the procedures for fetal ultrasonography, amniocentesis, and chorionic villi sampling.

Several tests are available to detect genetic disorders and assess fetal well-being. Here we describe fetal ultrasonography, amniocentesis, and chorionic villi sampling (CVS).

Fetal Ultrasonography

If there is a question about the normal progress of a pregnancy, fetal ultrasonography (ul-tra-son-OG-ra-fé) may be performed. By far the most common use of diagnostic ultrasound is to determine a more accurate fetal age when the date of conception is unclear. It is also used to confirm pregnancy, evaluate fetal viability and growth, determine fetal position, identify multiple pregnancies, identify fetal–maternal abnormalities, and serve as an adjunct to special procedures such as amniocentesis. During fetal ultrasonography, a transducer, an instrument that emits high-frequency sound waves, is passed back and forth over the abdomen. The reflected sound waves from the developing fetus are picked up by the transducer and converted to an on-screen image called a sonogram (see Table 1.3 on page 21). Because the urinary bladder serves as a landmark during the procedure, the patient needs to drink liquids before the procedure and not void urine to maintain a full bladder.

Amniocentesis

Amniocentesis (am’-ne-0-sen-TÉ-sis; amnio- = amnion; -centesis = puncture to remove fluid) involves withdrawing some of the amniotic fluid that bathes the developing fetus and analyzing the fetal cells and dissolved substances. It is used to test for the presence of certain genetic disorders, such as Down syndrome...
DS, hemophilia, Tay-Sachs disease, sickle-cell disease, and certain muscular dystrophies. It is also used to help determine survivability of the fetus. The test is usually done at 14–18 weeks of gestation. All gross chromosomal abnormalities and over 50 biochemical defects can be detected through amniocentesis. It can also reveal the baby’s gender, which is important information for the diagnosis of sex-linked disorders, in which an abnormal gene carried by the mother affects her male offspring only (described on page 1167).

During amniocentesis, the position of the fetus and placenta is first identified using ultrasound and palpation. After the skin is prepared with an antiseptic and a local anesthetic is given, a hypodermic needle is inserted through the mother’s abdominal wall and into the amniotic cavity within the uterus. Then, 10 to 30 mL of fluid and suspended cells are aspirated (Figure 29.15a) for microscopic examination and biochemical testing. Elevated levels of alpha-fetoprotein (AFP) and acetylcholinesterase may indicate failure of the nervous system to develop properly, as occurs in spina bifida or anencephaly (absence of the cerebrum) or may be due to other developmental or chromosomal problems. Chromosome studies, which require growing the cells for 2–4 weeks in a culture medium, may reveal rearranged, missing, or extra chromosomes. Amniocentesis is performed only when a risk for genetic defects is suspected, because there is about a 0.5% chance of spontaneous abortion after the procedure.

**Figure 29.15** Amniocentesis and chorionic villi sampling.

![Figure 29.15](image)

To detect genetic abnormalities, amniocentesis is performed at 14–16 weeks of gestation; chorionic villi sampling may be performed as early as 8 weeks of gestation.

**Chorionic Villi Sampling**

In chorionic villi sampling (ko-rē-ON-ik VIL-i) or CVS, a catheter is guided through the vagina and cervix of the uterus and then advanced to the chorionic villi under ultrasound guidance (Figure 29.15b). About 30 milligrams of tissue are suctioned out and prepared for chromosomal analysis. Alternatively, the chorionic villi can be sampled by inserting a needle through the abdominal cavity, as performed in amniocentesis.

CVS can identify the same defects as amniocentesis because chorion cells and fetal cells contain the same genome. CVS offers several advantages over amniocentesis: It can be performed as early as eight weeks of gestation, and test results are available in only a few days, permitting an earlier decision on whether to continue the pregnancy. However, CVS is slightly riskier than amniocentesis; after the procedure there is a 1–2% chance of spontaneous abortion.

**Noninvasive Prenatal Tests**

Currently, chorionic villi testing and amniocentesis are the only useful ways to obtain fetal tissue for prenatal testing of gene defects. While these invasive procedures pose relatively little risk when performed by experts, much work has been done to develop noninvasive prenatal tests, which do not require the penetration of any embryonic structure. The goal is to develop
accurate, safe, more efficient, and less expensive tests for screening a large population.

The first such test developed was the **maternal alpha-fetoprotein (AFP) test**. In this test, the mother’s blood is analyzed for the presence of AFP, a protein synthesized in the fetus that passes into the maternal circulation. The highest levels of AFP normally occur during weeks 12 through 15 of pregnancy. Later, AFP is not produced, and its concentration decreases to a very low level both in the fetus and in maternal blood. A high level of AFP after week 16 usually indicates that the fetus has a neural tube defect, such as spina bifida or anencephaly. Because the test is 95% accurate, it is now recommended that all pregnant women be tested for AFP. A newer test (Quad AFP Plus) probes maternal blood for AFP and three other molecules. The test permits prenatal screening for Down syndrome, trisomy 18, and neural tube defects; it also helps predict the delivery date and may reveal the presence of twins.

**CHECKPOINT**

26. What conditions can be detected using fetal ultrasonography, amniocentesis, and chorionic villi sampling? What are the advantages of noninvasive prenatal tests?

**MATERNAL CHANGES DURING PREGNANCY**

<table>
<thead>
<tr>
<th>OBJECTIVES</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Describe the sources and functions of the hormones secreted during pregnancy.</td>
</tr>
<tr>
<td>• Describe the hormonal, anatomical, and physiological changes in the mother during pregnancy.</td>
</tr>
</tbody>
</table>

**Hormones of Pregnancy**

During the first 3 to 4 months of pregnancy, the corpus luteum in the ovary continues to secrete progesterone and estrogens, which maintain the lining of the uterus during pregnancy and prepare the mammary glands to secrete milk. The amounts secreted by the corpus luteum, however, are only slightly more than those produced after ovulation in a normal menstrual cycle. From the third month through the remainder of the pregnancy, the placenta itself provides the high levels of progesterone and estrogens required. As noted previously, the chorion secretes **human chorionic gonadotropin (hCG)** into the blood. In turn, hCG stimulates the corpus luteum to continue production of progesterone and estrogens—an activity required to prevent menstruation and for the continued attachment of the embryo and fetus to the lining of the uterus (Figure 29.16a). By the eighth day after fertilization, hCG can be detected in the blood and urine of a pregnant woman. Peak secretion of hCG occurs at about the ninth week of pregnancy (Figure 29.16b). During the fourth and fifth months the hCG level decreases sharply and then levels off until childbirth.

The chorion begins to secrete estrogens after the first 3 or 4 weeks of pregnancy and progesterone by the sixth week. These hormones are secreted in increasing quantities until the time of birth (Figure 29.16b). By the fourth month, when the placenta is fully established, the secretion of hCG is greatly reduced, and the secretions of the corpus luteum are no longer essential. A high level of progesterone ensures that the uterine myometrium is relaxed and that the cervix is tightly closed. After delivery, estrogens and progesterone in the blood decrease to normal levels.

**Relaxin**, a hormone produced first by the corpus luteum of the ovary and later by the placenta, increases the flexibility of the pubic symphysis and ligaments of the sacroiliac and sacrococcygeal joints and helps dilate the uterine cervix during labor. Both of these actions ease delivery of the baby.

A third hormone produced by the chorion of the placenta is **human chorionic somatomammotropin (hCS)**, also known as **human placental lactogen (hPL)**. The rate of secretion of hCS increases in proportion to placental mass, reaching maximum levels after 32 weeks and remaining relatively constant after that. It is thought to help prepare the mammary glands for lactation, enhance maternal growth by increasing protein synthesis, and regulate certain aspects of metabolism in both mother and fetus. For example, hCS decreases the use of glucose by the mother and promotes the release of fatty acids from her adipose tissue, making more glucose available to the fetus.

The hormone most recently found to be produced by the placenta is **corticotropin-releasing hormone (CRH)**, which in nonpregnant people is secreted only by neurosecretory cells in the hypothalamus. CRH is now thought to be part of the “clock” that establishes the timing of birth. Secretion of CRH by the placenta begins at about 12 weeks and increases enormously toward the end of pregnancy. Women who have higher levels of CRH earlier in pregnancy are more likely to deliver prematurely; those who have low levels are more likely to deliver after their due date. CRH from the placenta has a second important effect: It increases secretion of cortisol, which is needed for maturation of the fetal lungs and the production of surfactant (see page 888).

**CLINICAL CONNECTION | Early Pregnancy Tests**

Early pregnancy tests detect the tiny amounts of human chorionic gonadotropin (hCG) in the urine that begin to be excreted about 8 days after fertilization. The test kits can detect pregnancy as early as the first day of a missed menstrual period—that is, at about 14 days after fertilization. Chemicals in the kits produce a color change if a reaction occurs between hCG in the urine and hCG antibodies included in the kit.

Several of the test kits available at pharmacies are as sensitive and accurate as test methods used in many hospitals. Still, false-negative and false-positive results can occur. A false-negative result (the test is negative, but the woman is pregnant) may be due to testing too soon or to an ectopic pregnancy. A false-positive result (the test is positive, but the woman is not pregnant) may be due to excess protein or blood in the urine or to hCG production due to a rare type of uterine cancer. Thiazide diuretics, hormones, steroids, and thyroid drugs may also affect the outcome of an early pregnancy test.
The corpus luteum produces progesterone and estrogens during the first 3–4 months of pregnancy, after which time the placenta assumes this function.

---

**Which hormone is detected by early pregnancy tests?**
Changes During Pregnancy

Near the end of the third month of pregnancy, the uterus occupies most of the pelvic cavity. As the fetus continues to grow, the uterus extends higher and higher into the abdominal cavity. Toward the end of a full-term pregnancy, the uterus fills nearly the entire abdominal cavity, reaching above the costal margin nearly to the xiphoid process of the sternum (Figure 29.17). It pushes the maternal intestines, liver, and stomach superiorly, elevates the diaphragm, and widens the thoracic cavity. Pressure on the stomach may force the stomach contents superiorly into the esophagus, resulting in heartburn. In the pelvic cavity, compression of the ureters and urinary bladder occurs.

Pregnancy-induced physiological changes also occur, including weight gain due to the fetus, amniotic fluid, the placenta, uterine enlargement, and increased total body water; increased storage of proteins, triglycerides, and minerals; marked breast enlargement in preparation for lactation; and lower back pain due to lordosis (hollow back).

Several changes occur in the maternal cardiovascular system. Stroke volume increases by about 30% and cardiac output rises by 20–30% due to increased maternal blood flow to the placenta and increased metabolism. Heart rate increases 10–15% and blood volume increases 30–50%, mostly during the second half of pregnancy. These increases are necessary to meet the additional demands of the fetus for nutrients and oxygen. When a pregnant woman is lying on her back, the enlarged uterus may compress the aorta, resulting in diminished blood flow to the uterus. Compression of the inferior vena cava also decreases venous return, which leads to edema in the lower limbs and may

Figure 29.17 Normal fetal location and position at the end of a full-term pregnancy.

The gestation period is the time interval (about 38 weeks) from fertilization to birth.

What hormone increases the flexibility of the pubic symphysis and helps dilate the cervix of the uterus to ease delivery of the baby?
CHAPTER 29  •  DEVELOPMENT AND INHERITANCE

1158

produce varicose veins. Compression of the renal artery can lead to renal hypertension.

Respiratory function is also altered during pregnancy to meet the added oxygen demands of the fetus. Tidal volume can increase by 30–40%, expiratory reserve volume can be reduced by up to 40%, functional residual capacity can decline by up to 25%, minute ventilation (the total volume of air inhaled and exhaled each minute) can increase by up to 40%, airway resistance in the bronchial tree can decline by 30–40%, and total body oxygen consumption can increase by about 10–20%. Dyspnea (difficult breathing) also occurs.

The digestive system also undergoes changes. Pregnant women experience an increase in appetite due to the added nutritional demands of the fetus. A general decrease in GI tract motility can cause constipation, delay gastric emptying time, and produce nausea, vomiting, and heartburn.

Pressure on the urinary bladder by the enlarging uterus can produce urinary symptoms, such as increased frequency and urgency of urination, and stress incontinence. An increase in renal plasma flow up to 35% and an increase in glomerular filtration rate up to 40% increase the renal filtering capacity, which allows faster elimination of the extra wastes produced by the fetus.

Changes in the skin during pregnancy are more apparent in some women than in others. Some women experience increased pigmentation around the eyes and cheekbones in a masklike pattern (chloasma), in the areolae of the breasts, and in the linea alba of the lower abdomen (linea nigra). Striae (stretch marks) over the abdomen can occur as the uterus enlarges, and hair loss increases.

Changes in the reproductive system include edema and increased vascularity of the vulva and increased pliability and vascularity of the vagina. The uterus increases from its nonpregnant mass of 60–80 g to 900–1200 g at term because of hyperplasia of muscle fibers in the myometrium in early pregnancy and hypertrophy of muscle fibers during the second and third trimesters.

• CLINICAL CONNECTION  Pregnancy-Induced Hypertension

About 10–15% of all pregnant women in the United States experience pregnancy-induced hypertension (PIH), an elevated blood pressure that is associated with pregnancy. The major cause is preeclampsia (pré-é-KLAMP-sè-a), an abnormal condition of pregnancy characterized by sudden hypertension, large amounts of protein in the urine, and generalized edema that typically appears after the 20th week of pregnancy. Other signs and symptoms are generalized edema, blurred vision, and headaches. Preeclampsia might be related to an autoimmune or allergic reaction resulting from the presence of a fetus. Treatment involves bed rest and various drugs. When the condition is also associated with convulsions and coma, it is termed eclampsia.

• CHECKPOINT

27. List the hormones involved in pregnancy, and describe the functions of each.

28. What structural and functional changes occur in the mother during pregnancy?

EXERCISE AND PREGNANCY

• OBJECTIVE

- Explain the effects of pregnancy on exercise and of exercise on pregnancy.

Only a few changes in early pregnancy affect the ability to exercise. A pregnant woman may tire more easily than usual, or morning sickness may interfere with regular exercise. As the pregnancy progresses, weight is gained and posture changes, so more energy is needed to perform activities, and certain maneuvers (sudden stopping, changes in direction, rapid movements) are more difficult to execute. In addition, certain joints, especially the pubic symphysis, become less stable in response to the increased level of the hormone relaxin. As compensation, many mothers-to-be walk with widely spread legs and a shuffling motion.

Although blood shifts from viscera (including the uterus) to the muscles and skin during exercise, there is no evidence of inadequate blood flow to the placenta. The heat generated during exercise may cause dehydration and further increase body temperature. Especially during early pregnancy, excessive exercise and heat buildup should be avoided because elevated body temperature has been implicated in neural tube defects. Exercise has no known effect on lactation, provided a woman remains hydrated and wears a bra that provides good support. Overall, moderate physical activity does not endanger the fetus of a healthy woman who has a normal pregnancy. However, any physical activity that might endanger the fetus should be avoided.

Among the benefits of exercise to the mother during pregnancy are a greater sense of well-being and fewer physical complaints.

• CHECKPOINT

29. Which changes in pregnancy have an effect on the ability to exercise?

LABOR

• OBJECTIVE

- Explain the events associated with the three stages of labor.

Labor is the process by which the fetus is expelled from the uterus through the vagina, also referred to as giving birth. A synonym for labor is parturition (par'-toor-ISH-un; parturit- = childbirth).

The onset of labor is determined by complex interactions of several placental and fetal hormones. Because progesterone inhibits uterine contractions, labor cannot take place until its effects are diminished. Toward the end of gestation, the levels of estrogens in the mother’s blood rise sharply, producing changes that overcome the inhibiting effects of progesterone. The rise in estrogens results from increasing secretion by the placenta of
corticotropin-releasing hormone, which stimulates the anterior pituitary gland of the fetus to secrete ACTH (adrenocorticotropic hormone). In turn, ACTH stimulates the fetal adrenal gland to secrete cortisol and dehydroepiandrosterone (DHEA), the major adrenal androgen. The placenta then converts DHEA into an estrogen. High levels of estrogen cause the number of receptors for oxytocin on uterine muscle fibers to increase, and cause uterine muscle fibers to form gap junctions with one another. Oxytocin released by the posterior pituitary stimulates uterine contractions, and relaxin from the placenta assists by increasing the flexibility of the pubic symphysis and helping dilate the uterine cervix. Estrogen also stimulates the placenta to release prostaglandins, which induce production of enzymes that digest collagen fibers in the cervix, causing it to soften.

Control of labor contractions during parturition occurs via a positive feedback cycle (see Figure 1.4 on page 11). Contraction of the uterine myometrium force the baby’s head or body into the cervix, distending (stretching) the cervix. Stretch receptors in the cervix send nerve impulses to neurosecretory cells in the hypothalamus, causing them to release oxytocin into blood capillaries of the posterior pituitary gland. Oxytocin then is carried by the blood to the uterus, where it stimulates the myometrium to contract more forcefully. As the contractions intensify, the baby’s body stretches the cervix still more, and the resulting nerve impulses stimulate the secretion of yet more oxytocin. With birth of the infant, the positive feedback cycle is broken because cervical distension suddenly lessens.

Uterine contractions occur in waves (quite similar to the peristaltic waves of the gastrointestinal tract) that start at the top of the uterus and move downward, eventually expelling the fetus. True labor begins when uterine contractions occur at regular intervals, usually producing pain. As the interval between contractions shortens, the contractions intensify. Another symptom of true labor in some women is localization of pain in the back that is intensified by walking. The most reliable indicator of true labor is dilation of the cervix and the “show,” a discharge of a blood-containing mucus into the cervical canal. In false labor, pain is felt in the abdomen at irregular intervals, but it does not intensify and walking does not alter it significantly. There is no “show” and no cervical dilation.

True labor can be divided into three stages (Figure 29.18):

1. **Stage of dilation.** The time from the onset of labor to the complete dilation of the cervix is the stage of dilation. This stage, which typically lasts 6–12 hours, features regular contractions of the uterus, usually a rupturing of the amniotic sac, and complete dilation (to 10 cm) of the cervix. If the amniotic sac does not rupture spontaneously, it is ruptured intentionally.

2. **Stage of expulsion.** The time (10 minutes to several hours) from complete cervical dilation to delivery of the baby is the stage of expulsion.

3. **Placental stage.** The time (5–30 minutes or more) after delivery until the placenta or “afterbirth” is expelled by powerful uterine contractions is the placental stage. These contrac-

? What event marks the beginning of the stage of expulsion?

As a rule, labor lasts longer with first babies, typically about 14 hours. For women who have previously given birth, the average duration of labor is about 8 hours—although the time varies enormously among births. Because the fetus may be squeezed through the birth canal (cervix and vagina) for up to several hours, the fetus is stressed during childbirth: The fetal head is
compressed, and the fetus undergoes some degree of intermittent hypoxia due to compression of the umbilical cord and the placenta during uterine contractions. In response to this stress, the fetal adrenal medullae secrete very high levels of epinephrine and norepinephrine, the “fight-or-flight” hormones. Much of the protection against the stresses of parturition, as well as preparation of the infant for surviving extrauterine life, is provided by these hormones. Among other functions, epinephrine and norepinephrine clear the lungs and alter their physiology in readiness for breathing air, mobilize readily usable nutrients for cellular metabolism, and promote an increased flow of blood to the brain and heart.

About 7% of pregnant women do not deliver by 2 weeks after their due date. Such cases carry an increased risk of brain damage to the fetus, and even fetal death, due to inadequate supplies of oxygen and nutrients from an aging placenta. Post-term deliveries may be facilitated by inducing labor, initiated by administration of oxytocin (Pitocin®), or by surgical delivery (cesarean section).

Following the delivery of the baby and placenta is a 6-week period during which the maternal reproductive organs and physiology return to the prepregnancy state. This period is called the puerperium (pu²-er-PÆ-ë-um). Through a process of tissue catabolism, the uterus undergoes a remarkable reduction in size, called involution (in²-vÔ-LOO-shun), especially in lactating women. The cervix loses its elasticity and regains its prepregnancy firmness. For 2–4 weeks after delivery, women have a uterine discharge called lochia (LO-kÈ-a), which consists initially of blood and later of serous fluid derived from the former site of the placenta.

**CLINICAL CONNECTION**  
**Dystocia and Cesarean Section**

Dystocia (dis-TÔ-së-a; dys- = painful or difficult; tocc- = birth), or difficult labor, may result either from an abnormal position (presentation) of the fetus or a birth canal of inadequate size to permit vaginal delivery. In a breech presentation, for example, the fetal buttocks or lower limbs, rather than the head, enter the birth canal first; this occurs most often in premature births. If fetal or maternal distress prevents a vaginal birth, the baby may be delivered surgically through an abdominal incision. A low, horizontal cut is made through the abdominal wall and lower portion of the uterus, through which the baby and placenta are removed. Even though it is popularly associated with the birth of Julius Caesar, the true reason this procedure is termed a cesarean section (C-section) is because it was described in Roman Law, lex cesarea, about 600 years before Julius Caesar was born. Even a history of multiple C-sections need not exclude a pregnant woman from attempting a vaginal delivery.

**CHECKPOINT**

30. What hormonal changes induce labor?
31. What is the difference between false labor and true labor?
32. What happens during the stage of dilation, the stage of expulsion, and the placental stage of true labor?

**ADJUSTMENTS OF THE INFANT AT BIRTH**

**OBJECTIVE**

- Explain the respiratory and cardiovascular adjustments that occur in an infant at birth.

During pregnancy, the embryo (and later the fetus) is totally dependent on the mother for its existence. The mother supplies the fetus with oxygen and nutrients, eliminates its carbon dioxide and other wastes, protects it against shocks and temperature changes, and provides antibodies that confer protection against certain harmful microbes. At birth, a physiologically mature baby becomes much more self-supporting, and the newborn’s body systems must make various adjustments. The most dramatic changes occur in the respiratory and cardiovascular systems.

**Respiratory Adjustments**

The reason that the fetus depends entirely on the mother for obtaining oxygen and eliminating carbon dioxide is that the fetal lungs are either collapsed or partially filled with amniotic fluid. The production of surfactant begins by the end of the sixth month of development. Because the respiratory system is fairly well developed at least 2 months before birth, premature babies delivered at 7 months are able to breathe and cry. After delivery, the baby’s supply of oxygen from the mother ceases, and any amniotic fluid in the fetal lungs is absorbed. Because carbon dioxide is no longer being removed, it builds up in the blood. A rising CO₂ level stimulates the respiratory center in the medulla oblongata, causing the respiratory muscles to contract, and the baby to draw his or her first breath. Because the first inspiration is unusually deep, as the lungs contain no air, the baby also exhales vigorously and naturally cries. A full-term baby may breathe 45 times a minute for the first 2 weeks after birth. Breathing rate gradually declines until it approaches a normal rate of 12 breaths per minute.

**Cardiovascular Adjustments**

After the baby’s first inspiration, the cardiovascular system must make several adjustments (see Figure 21.30 on page 821). Closure of the foramen ovale between the atria of the fetal heart, which occurs at the moment of birth, diverts deoxygenated blood to the lungs for the first time. The foramen ovale is closed by two flaps of septal heart tissue that fold together and permanently fuse. The remnant of the foramen ovale is the fossa ovalis.

Once the lungs begin to function, the ductus arteriosus shuts off due to contractions of smooth muscle in its wall, and it becomes the ligamentum arteriosum. The muscle contraction is probably mediated by the polypeptide bradykinin, released from the lungs during their initial inflation. The ductus arteriosus generally does not close completely until about 3 months after birth. Prolonged incomplete closure results in a condition called patent ductus arteriosus (see Figure 20.23b on page 753).
After the umbilical cord is tied off and severed and blood no longer flows through the umbilical arteries, they fill with connective tissue, and their distal portions become the medial umbilical ligaments. The umbilical vein then becomes the ligamentum teres (round ligament) of the liver.

In the fetus, the ductus venosus connects the umbilical vein directly with the inferior vena cava, allowing blood from the placenta to bypass the fetal liver. When the umbilical cord is severed, the ductus venosus collapses, and venous blood from the visceras of the fetus flows into the hepatic portal vein to the liver and then via the hepatic vein to the inferior vena cava. The remnant of the ductus venosus becomes the ligamentum venosum.

At birth, an infant’s pulse may range from 120 to 160 beats per minute and may go as high as 180 upon excitation. After birth, oxygen use increases, which stimulates an increase in the rate of red blood cell and hemoglobin production. The white blood cell count at birth is very high—sometimes as much as 45,000 cells per microliter—but the count decreases rapidly by the seventh day. Recall that the white blood cell count of an adult is 5000–10,000 cells per microliter.

**CLINICAL CONNECTION Premature Infants**

Delivery of a physiologically immature baby carries certain risks. A premature infant or “preemie” is generally considered a baby who weighs less than 2500 g (5.5 lb) at birth. Poor prenatal care, drug abuse, history of a previous premature delivery, and mother’s age below 16 or above 35 increase the chance of premature delivery. The body of a premature infant is not yet ready to sustain some critical functions, and thus its survival is uncertain without medical intervention. The major problem after delivery of an infant under 36 weeks of gestation is respiratory distress syndrome (RDS) of the newborn due to insufficient surfactant. RDS can be eased by use of artificial surfactant and a ventilator that delivers oxygen until the lungs can operate on their own.

**CHECKPOINT**

33. Why are respiratory and cardiovascular adjustments so important at birth?

---

**THE PHYSIOLOGY OF LACTATION**

**OBJECTIVE**

- Discuss the physiology and hormonal control of lactation.

Lactation (lak'-TÄ-shun) is the secretion and ejection of milk from the mammary glands. A principal hormone in promoting milk synthesis and secretion is prolactin (PRL), which is secreted from the anterior pituitary gland. Even though prolactin levels increase as the pregnancy progresses, no milk secretion occurs because progesterone inhibits the effects of prolactin. After delivery, the levels of estrogens and progesterone in the mother’s blood decrease, and the inhibition is removed. The principal stimulus in maintaining prolactin secretion during lactation is the sucking action of the infant. Suckling initiates nerve impulses from stretch receptors in the nipples to the hypothalamus; the impulses decrease hypothalamic release of prolactin-inhibiting hormone (PIH) and increase release of prolactin-releasing hormone (PRH), so more prolactin is released by the anterior pituitary.

Oxytocin causes release of milk into the mammary ducts via the milk ejection reflex (Figure 29.19). Milk formed by the...

**Figure 29.19** The milk ejection reflex, a positive feedback cycle.

---

What is another function of oxytocin?
glandular cells of the breasts is stored until the baby begins active sucking. Stimulation of touch receptors in the nipple initiates sensory nerve impulses that are relayed to the hypothalamus. In response, secretion of oxytocin from the posterior pituitary increases. Carried by the bloodstream to the mammary glands, oxytocin stimulates contraction of myoepithelial (smooth-muscle-like) cells surrounding the glandular cells and ducts. The resulting compression moves the milk from the alveoli of the mammary glands into the mammary ducts, where it can be sucked. This process is termed milk ejection (let-down). Even though the actual ejection of milk does not occur until 30–60 seconds after nursing begins (the latent period), some milk stored in lactiferous sinuses near the nipple is available during the latent period. Stimuli other than suckling, such as hearing a baby’s cry or touching the mother’s genitals, also can trigger oxytocin release and milk ejection. The suckling stimulation that produces the release of oxytocin also inhibits the release of PIH; this results in increased secretion of prolactin, which maintains lactation.

During late pregnancy and the first few days after birth, the mammary glands secrete a cloudy fluid called colostrum. Although it is not as nutritious as milk—it contains less lactose and virtually no fat—colostrum serves adequately until the appearance of true milk on about the fourth day. Colostrum and maternal milk contain important antibodies that protect the infant during the first few months of life.

Following birth of the infant, the prolactin level starts to return to the nonpregnant level. However, each time the mother nurses the infant, nerve impulses from the nipples to the hypothalamus increase the release of PRH (and decrease the release of PIH), resulting in a tenfold increase in prolactin secretion by the anterior pituitary that lasts about an hour. Prolactin acts on the mammary glands to provide milk for the next nursing period. If this surge of prolactin is blocked by injury or disease, or if nursing is discontinued, the mammary glands lose their ability to secrete milk in only a few days. Even though milk secretion normally decreases considerably within 7–9 months after birth, it can continue for several years if nursing or breast-feeding continues.

Lactation often blocks ovarian cycles for the first few months following delivery, if the frequency of sucking is about 8–10 times a day. This effect is inconsistent, however, and ovulation commonly precedes the first menstrual period after delivery of a baby. As a result, the mother can never be certain she is not fertile. Breast-feeding is therefore an unreliable birth control measure. The suppression of ovulation during lactation is believed to occur as follows: During breast-feeding, neural input from the nipple reaches the hypothalamus and causes it to produce neurotransmitters that suppress the release of gonadotropin-releasing hormone (GnRH). As a result, production of LH and FSH decreases, and ovulation is inhibited.

A primary benefit of breast-feeding is nutritional: Human milk is a sterile solution that contains amounts of fatty acids, lactose, amino acids, minerals, vitamins, and water that are ideal for the baby’s digestion, brain development, and growth. Breast-feeding also benefits infants by providing the following:

- **Beneficial cells.** Several types of white blood cells are present in breast milk. Neutrophils and macrophages serve as phagocytic agents to microbes in the baby’s gastrointestinal tract. Macrophages also produce lysozyme and other immune system components. Plasma cells, which develop from B lymphocytes, produce antibodies against specific microbes, and T lymphocytes kill microbes directly or help mobilize other defenses.

- **Beneficial molecules.** Breast milk also contains an abundance of beneficial molecules. Maternal IgA antibodies in breast milk bind to microbes in the baby’s gastrointestinal tract and prevent their migration into other body tissues. Because a mother produces antibodies to whatever disease-causing microbes are present in her environment, her breast milk offers protection against the specific infectious agents to which her baby is also exposed. Additionally, two milk proteins bind to nutrients that many bacteria need to grow and survive: B12-binding protein ties up vitamin B12, and lactoferrin ties up iron. Some fatty acids can kill certain viruses by disrupting their membranes, and lysozyme kills bacteria by disrupting their cell walls. Finally, interferons enhance the antimicrobial activity of immune cells.

- **Decreased incidence of diseases later in life.** Breast-feeding provides children with a slight reduction in risk of lymphoma, heart disease, allergies, respiratory and gastrointestinal infections, ear infections, diarrhea, diabetes mellitus, and meningitis.

- **Miscellaneous benefits.** Breast-feeding supports optimal infant growth, enhances intellectual and neurological development, and fosters mother–infant relations by establishing early and prolonged contact between them. Compared to cow’s milk, the fats and iron in breast milk are more easily absorbed, the proteins in breast milk are more readily metabolized, and the lower sodium content of breast milk is more suited to an infant’s needs. Premature infants benefit even more from breast-feeding because the milk produced by mothers of premature infants seems to be specially adapted to the infant’s needs; it has a higher protein content than the milk of mothers of full-term infants. Finally, a baby is less likely to have an allergic reaction to its mother’s milk than to milk from another source.

Years before oxytocin was discovered, it was common practice in midwifery to let a first-born twin nurse at the mother’s breast to speed the birth of the second child. Now we know why this practice is helpful—it stimulates the release of oxytocin. Even after a single birth, nursing promotes expulsion of the placenta (afterbirth) and helps the uterus return to its normal size. Synthetic oxytocin (Pitocin) is often given to induce labor or to increase uterine tone and control hemorrhage just after parturition.

### CHECKPOINT

34. Which hormones contribute to lactation? What is the function of each?

35. What are the benefits of breast-feeding over bottle-feeding?
INHERITANCE

**OBJECTIVE**
- Define inheritance, and explain the inheritance of dominant, recessive, complex, and sex-linked traits.

As previously indicated, the genetic material of a father and a mother unite when a sperm cell fuses with a secondary oocyte to form a zygote. Children resemble their parents because they inherit traits passed down from both parents. We now examine some of the principles involved in that process, called inheritance.

**Inheritance** is the passage of hereditary traits from one generation to the next. It is the process by which you acquired your characteristics from your parents and may transmit some of your traits to your children. The branch of biology that deals with inheritance is called genetics (je-NET-iks). The area of health care that offers advice on genetic problems (or potential problems) is called genetic counseling.

**Genotype and Phenotype**

As you have already learned, the nuclei of all human cells except gametes contain 23 pairs of chromosomes—the diploid number (2n). One chromosome in each pair came from the mother, and the other came from the father. Each of these two homologues contains genes that control the same traits. If one chromosome of the pair contains a gene for body hair, for example, its homologue will contain a gene for body hair in the same position. Alternative forms of a gene that code for the same trait and are on the same chromosome are called alleles (ah-LÉLZ). One allele of the previously mentioned body hair gene might code for coarse hair, and another might code for fine hair. A mutation (mú-TÁ-shun; muta- = change) is a permanent heritable change in an allele that produces a different variant of the same trait.

The relationship of genes to heredity is illustrated by examining the alleles involved in a disorder called phenylketonuria (PKU). People with PKU (see page 995) are unable to manufacture the enzyme phenylalanine hydroxylase. The allele that codes for phenylalanine hydroxylase is symbolized as P; the mutated allele that fails to produce a functional enzyme is represented by p. The chart in Figure 29.20, which shows the possible combinations of gametes from two parents who each have one P and one p allele, is called a Punnett square. In constructing a Punnett square, the possible paternal alleles in sperm are written at the left side and the possible maternal alleles in ova (or secondary oocytes) are written at the top. The four spaces on the chart show how the alleles can combine in zygotes formed by the union of these sperm and ova to produce the three different combinations of genes, or genotypes (JÉ-nó-tips): PP, Pp, or pp. Notice from the Punnett square that 25% of the offspring will have the PP genotype, 50% will have the Pp genotype, and 25% will have the pp genotype. (These percentages are probabilities only; parents who have four children won’t necessarily end up with one with PKU.) People who inherit PP or Pp genotypes do not have PKU; those with a pp genotype suffer from the disorder. Although people with a Pp genotype have one PKU allele (p), the allele that codes for the normal trait (P) masks the presence of the PKU allele. An allele that dominates or masks the presence of another allele and is fully expressed (P in this example) is said to be a dominant allele, and the trait expressed is called a dominant trait. The allele whose presence is completely masked (p in this example) is said to be a recessive allele, and the trait it controls is called a recessive trait.

By tradition, the symbols for genes are written in italics, with dominant alleles written in capital letters and recessive alleles in lowercase letters. A person with the same alleles on homologous chromosomes (for example, PP or pp) is said to be homozygous for the trait. PP is homozygous dominant, and pp is homozygous recessive. An individual with different alleles on homologous chromosomes (for example, Pp) is said to be heterozygous for the trait.

**Phenotype** (FÉ-nó-típ; pheno- = showing) refers to how the genetic makeup is expressed in the body; it is the physical or outward expression of a gene. A person with Pp (a heterozygote) has a different genotype from a person with PP (a homozygote), but both have the same phenotype—normal production of phenylalanine hydroxylase. Heterozygous individuals who carry a recessive gene but do not express it (Pp) can pass the gene on to their children.

**Figure 29.20** Inheritance of phenylketonuria (PKU).

Genotype refers to genetic makeup; phenotype refers to the physical or outward expression of a gene.

If parents have the genotypes shown here, what is the chance that their first child will have PKU? What is the chance of PKU occurring in their second child?
to their offspring. Such individuals are called carriers of the recessive gene.

Most genes give rise to the same phenotype whether they are inherited from the mother or the father. In a few cases, however, the phenotype is dramatically different, depending on the parental origin. This surprising phenomenon, first appreciated in the 1980s, is called genomic imprinting. In humans, the abnormalities most clearly associated with mutation of an imprinted gene are Angelman syndrome (mental retardation, ataxia, seizures, and minimal speech), which results when the gene for a particular abnormal trait is inherited from the mother, and Prader-Willi syndrome (short stature, mental retardation, obesity, poor responsiveness to external stimuli, and sexual immaturity), which results when it is inherited from the father.

Alleles that code for normal traits do not always dominate over those that code for abnormal ones, but dominant alleles for severe disorders usually are lethal and cause death of the embryo or fetus. One exception is Huntington disease (HD) (see page 588), which is caused by a dominant allele whose effects do not become manifest until adulthood. Both homozygous dominant and heterozygous people exhibit the disease; homozygous recessive people are normal. HD causes progressive degeneration of the nervous system and eventual death, but because symptoms typically do not appear until after age 30 or 40, many afflicted individuals will already have passed on the allele for the condition to their children by the time they discover they have the disease.

Occasionally an error in cell division, called nondisjunction, results in an abnormal number of chromosomes. In this situation, homologous chromosomes (during meiosis I) or sister chromatids (during anaphase of mitosis or meiosis II) fail to separate properly. See Figure 3.34 on page 99. A cell from which one or more chromosomes has been added or deleted is called an aneuploid (AN-ú-ployd). A monosomic cell (2n − 1) is missing a chromosome; a trisomic cell (2n + 1) has an extra chromosome. Most cases of Down syndrome (see page 1169) are aneuploid disorders in which there is trisomy of chromosome 21. Nondisjunction usually occurs during gametogenesis (meiosis), but about 2% of Down syndrome cases result from nondisjunction during mitotic divisions in early embryonic development.

Another error in meiosis is a translocation. In this case, two chromosomes that are not homologous break and interchange portions of their chromosomes. The individual who has a translocation may be perfectly normal if no loss of genetic material took place when the rearrangement occurred. However, some of the person’s gametes may not contain the correct amount and type of genetic material. About 3% of Down syndrome cases result from a translocation of part of chromosome 21 to another chromosome, usually chromosome 14 or 15. The individual who has this translocation is normal and does not even know that he or she is a “carrier.” When such a carrier produces gametes, however, some gametes end up with a whole chromosome 21 plus another chromosome with the translocated fragment of chromosome 21. Upon fertilization, the zygote then has three, rather than two, copies of that part of chromosome 21.

Table 29.3 lists some dominant and recessive inherited structural and functional traits in humans.

**Variations on Dominant–Recessive Inheritance**

Most patterns of inheritance do not conform to the simple dominant–recessive inheritance we have just described, in which only dominant and recessive alleles interact. The phenotypic expression of a particular gene may be influenced not only by which alleles are present, but also by other genes and by the environment. Most inherited traits are influenced by more than one gene, and, to complicate matters, most genes can influence more than one trait. Variations on dominant–recessive inheritance include incomplete dominance, multiple-allele inheritance, and complex inheritance.

**Incomplete Dominance**

In incomplete dominance, neither member of a pair of alleles is dominant over the other, and the heterozygote has a phenotype intermediate between the homozygous dominant and the homozygous recessive phenotypes. An example of incomplete dominance in humans is the inheritance of sickle-cell disease (SCD) (Figure 29.21). People with the homozygous dominant genotype HbA/HbA form normal hemoglobin; those with the homozygous recessive genotype HbS/HbS have sickle-cell disease and severe anemia. Although they are usually healthy, those with the heterozygous genotype HbA/HbS have minor problems with anemia because half their hemoglobin is normal and half is not. Heterozygotes are carriers, and they are said to have sickle-cell trait.

**Multiple-Allele Inheritance**

Although a single individual inherits only two alleles for each gene, some genes may have more than two alternative forms;
this is the basis for **multiple-allele inheritance**. One example of multiple-allele inheritance is the inheritance of the ABO blood group. The four blood types (phenotypes) of the ABO group—A, B, AB, and O—result from the inheritance of six combinations of three different alleles of a single gene called the I gene: (1) allele $I^A$ produces the A antigen, (2) allele $I^B$ produces the B antigen, and (3) allele $i$ produces neither A nor B antigen. Each person inherits two $I$-gene alleles, one from each parent, that give rise to the various phenotypes. The six possible genotypes produce four blood types, as follows:

<table>
<thead>
<tr>
<th>Genotype</th>
<th>Blood type (phenotype)</th>
</tr>
</thead>
<tbody>
<tr>
<td>$I^A I^A$ or $I^A i$</td>
<td>A</td>
</tr>
<tr>
<td>$I^B I^B$ or $I^B i$</td>
<td>B</td>
</tr>
<tr>
<td>$I^A I^B$</td>
<td>AB</td>
</tr>
<tr>
<td>$ii$</td>
<td>O</td>
</tr>
</tbody>
</table>

Notice that both $I^A$ and $I^B$ are inherited as dominant traits, and $i$ is inherited as a recessive trait. Because an individual with type AB blood has characteristics of both type A and type B red blood cells expressed in the phenotype, alleles $I^A$ and $I^B$ are said to be **codominant**. In other words, both genes are expressed equally in the heterozygote. Depending on the parental blood types, different offspring may have blood types different from each other. **Figure 29.22** shows the blood types offspring could inherit, given the blood types of their parents.

**Complex Inheritance**

Most inherited traits are not controlled by one gene, but instead by the combined effects of two or more genes, a situation referred to as **polygenic inheritance** (*poly-* = many), or the combined effects of many genes and environmental factors, a situation referred to as **complex inheritance**. Examples of complex traits include skin color, hair color, eye color, height, metabolism rate, and body build. In complex inheritance, one genotype can have many possible phenotypes, depending on the environment, or one phenotype can include many possible genotypes. For example, even though a person inherits several genes for tallness, full height potential may not be reached due to environmental factors, such as disease or malnutrition during the growth years. You have already learned that the risk of having a child with a neural tube defect is greater in pregnant women who lack adequate folic acid in their diet; this is also considered an environmental factor. Because neural tube defects are more prevalent in some families than in others, however, one or more genes may also contribute.

Often, a complex trait shows a continuous gradation of small differences between extremes among individuals. It is relatively easy to predict the risk of passing on an undesirable trait that is due to a single dominant or recessive gene, but it is very difficult to make this prediction when the trait is complex. Such traits are difficult to follow in a family because the range of variation is large, the number of different genes involved usually is not known, and the impact of environmental factors may be incompletely understood.
Skin color is a good example of a complex trait. It depends on environmental factors such as sun exposure and nutrition, as well as on several genes. Suppose that skin color is controlled by three separate genes, each having two alleles: A, a; B, b; and C, c (Figure 29.23). A person with the genotype AABBCC is very dark skinned, an individual with the genotype aabbcc is very light skinned, and a person with the genotype AaBbCc has an intermediate skin color. Parents having an intermediate skin color may have children with very light, very dark, or intermediate skin color. Note that the P generation (parental generation) is the starting generation, the F1 generation (first filial generation) is produced from the P generation, and the F2 generation (second filial generation) is produced from the F1 generation.

Autosomes, Sex Chromosomes, and Sex Determination

When viewed under a microscope, the 46 human chromosomes in a normal somatic cell can be identified by their size, shape, and staining pattern to be members of 23 different pairs. An entire set of chromosomes arranged in decreasing order of size and according to the position of the centromere is called a karyotype (KAR-ē-o¯-tı¯p; karyo- = nucleus; -typos = model) (Figure 29.24). In 22 of the pairs, the homologous chromosomes look alike and have the same appearance in both males and females; these 22 pairs are called autosomes. The two members of the 23rd pair are termed the sex chromosomes; they look different in males and females. In females, the pair consists of two chromosomes called X chromosomes. One X chromosome is also present in males, but its mate is a much smaller chromosome called a Y chromosome. The Y chromosome has only 231 genes, less than 10% of the 2968 genes present on chromosome 1, the largest autosome.

When a spermatocyte undergoes meiosis to reduce its chromosome number, it gives rise to two sperm that contain an X chromosome and two sperm that contain a Y chromosome. Oocytes have no Y chromosomes and produce only X-containing gametes. If the secondary oocyte is fertilized by an X-bearing sperm, the offspring normally is female (XX). Fertilization by a Y-bearing sperm produces a male (XY). Thus, an individual’s sex is determined by the father’s chromosomes (Figure 29.25).

Both female and male embryos develop identically until about 7 weeks after fertilization. At that point, one or more genes set into motion a cascade of events that leads to the development of a male; in the absence of normal expression of the gene or genes, the female pattern of development occurs. It has been known since 1959 that the Y chromosome is needed to initiate male development. Experiments published in 1991 established that the prime male-determining gene is one called SRY (sex-determining region of the Y chromosome). When a small DNA fragment containing this gene was inserted into 11 female mouse embryos, three of them developed as males. (The researchers suspected that the gene failed to be integrated into the genetic material in the other eight.) SRY acts as a molecular switch to turn on the male pattern of development. Only if the SRY gene is present and functional in a fertilized ovum will the fetus develop testes and differentiate into a male; in the absence of SRY, the fetus will develop ovaries and differentiate into a female.
Case studies have confirmed the key role of \textit{SRY} in directing the male pattern of development in humans. In some cases, phenotypic females with an XY genotype were found to have mutated \textit{SRY} genes. These individuals failed to develop normally as males because their \textit{SRY} gene was defective. In other cases, phenotypic males with an XX genotype were found to have a small piece of the Y chromosome, including the \textit{SRY} gene, inserted into one of their X chromosomes.

**Sex-Linked Inheritance**

In addition to determining the sex of the offspring, the sex chromosomes are responsible for the transmission of several nonsexual traits. Many of the genes for these traits are present on X chromosomes but are absent from Y chromosomes. This feature produces a pattern of heredity called \textit{sex-linked inheritance} that is different from the patterns already described.

**Red–Green Color Blindness**

One example of sex-linked inheritance is \textit{red–green color blindness}, the most common type of color blindness. This condition is characterized by a deficiency in either red- or green-sensitive cones, so red and green are seen as the same color (either red or green, depending on which cone is present). The gene for red–green color blindness is a recessive one designated \textit{c}.

Normal color vision, designated \textit{C}, dominates. The \textit{C/c} genes are located only on the X chromosome, so the ability to see colors depends entirely on the X chromosomes. The possible combinations are as follows:

<table>
<thead>
<tr>
<th>Genotype</th>
<th>Phenotype</th>
</tr>
</thead>
<tbody>
<tr>
<td>(X^cX^c)</td>
<td>Normal female</td>
</tr>
<tr>
<td>(X^cX^c)</td>
<td>Normal female (but a carrier of the recessive gene)</td>
</tr>
<tr>
<td>(XX^c)</td>
<td>Red–green color-blind female</td>
</tr>
<tr>
<td>(X^cY)</td>
<td>Normal male</td>
</tr>
<tr>
<td>(XY)</td>
<td>Red–green color-blind male</td>
</tr>
</tbody>
</table>

Only females who have two \(X^c\) genes are red–green color blind. This rare situation can result only from the mating of a color-blind male and a color-blind or carrier female. Because males do not have a second X chromosome that could mask the trait, all males with an \(X^c\) gene will be red–green color blind. Figure 29.26 illustrates the inheritance of red–green color blindness in the offspring of a normal male and a carrier female.

Traits inherited in the manner just described are called \textit{sex-linked traits}. The most common type of \textit{hemophilia}—a condition in which the blood fails to clot or clots very slowly after an injury—is also a sex-linked trait. Like the trait for red–green color blindness and hemophilia are examples of sex-linked traits.

Figure 29.25 Sex determination.

Sex is determined at the time of fertilization by the presence or absence of a Y chromosome in the sperm.

**Figure 29.26** An example of the inheritance of red–green color blindness.

Red–green color blindness and hemophilia are examples of sex-linked traits.

[Diagram of sex determination and possible outcomes]

**Question:** What are all chromosomes other than the sex chromosomes called?

**Answer:** All chromosomes other than the sex chromosomes are called autosomes.

**Question:** What is the genotype of a red–green color-blind female?

**Answer:** The genotype of a red–green color-blind female is \(XX^c\).
color blindness, hemophilia is caused by a recessive gene. Other sex-linked traits in humans are fragile X syndrome, nonfunctional sweat glands, certain forms of diabetes, some types of deafness, uncontrollable rolling of the eyeballs, absence of central incisors, night blindness, one form of cataract, juvenile glaucoma, and juvenile muscular dystrophy.

**X-Chromosome Inactivation**

Because they have two X chromosomes in every cell (except developing oocytes), females have a double set of all genes on the X chromosome. A mechanism termed X-chromosome inactivation (lyonization) in effect reduces the X-chromosome genes to a single set in females. In each cell of a female’s body, one X chromosome is randomly and permanently inactivated early in development, and most of the genes of the inactivated X chromosome are not expressed (transcribed and translated). The nuclei of cells in female mammals contain a dark-staining body, called a Barr body, that is not present in the nuclei of cells in males. Geneticist Mary Lyon correctly predicted in 1961 that the Barr body is the inactivated X chromosome. During inactivation, chemical groups that prevent transcription into RNA are added to the X chromosome’s DNA. As a result, an inactivated X chromosome reacts differently to histological stains and has a different appearance than the rest of the DNA. In nondoning (interphase) cells, it remains tightly coiled and can be seen as a dark-staining body within the nucleus. In a blood smear, the Barr body of neutrophils is termed a “drumstick” because it looks like a tiny drumstick-shaped projection of the nucleus.

**CHECKPOINT**

36. What do the terms genotype, phenotype, dominant, recessive, homozygous, and heterozygous mean?
37. What are genomic imprinting and nondisjunction?
38. Define incomplete dominance. Give an example.
39. What is multiple-allele inheritance? Give an example.
40. Define complex inheritance and give an example.
41. Why does X-chromosome inactivation occur?

---

**Infertility**

**Female infertility**, or the inability to conceive, occurs in about 10% of all women of reproductive age in the United States. Female infertility may be caused by ovarian disease, obstruction of the uterine tubes, or conditions in which the uterus is not adequately prepared to receive a fertilized ovum. **Male infertility** (sterility) is an inability to fertilize a secondary oocyte; it does not imply erectile dysfunction (impotence). Male infertility requires production of adequate quantities of viable, normal sperm by the testes, unobstructed transport of sperm though the ducts, and satisfactory deposition in the vagina. The seminiferous tubules of the testes are sensitive to many factors—x-rays, infections, toxins, malnutrition, and higher-than-normal scrotal temperatures—that may cause degenerative changes and produce male sterility.

One cause of infertility in females is inadequate body fat. To begin and maintain a normal reproductive cycle, a female must have a minimum amount of body fat. Even a moderate deficiency of fat—10% to 15% below normal weight for height—may delay the onset of menstruation (menarche), inhibit ovulation during the reproductive cycle, or cause amenorrhea (cessation of menstruation). Both dieting and intensive exercise may reduce body fat below the minimum amount and lead to infertility that is reversible, if weight gain or reduction of intensive exercise or both occurs. Studies of very obese women indicate that they, like very lean ones, experience problems with amenorrhea and infertility. Males also experience reproductive problems in response to undernutrition and weight loss. For example, they produce less prostatic fluid and reduced numbers of sperm having decreased motility.

Many fertility-expanding techniques now exist for assisting infertile couples to have a baby. The birth of Louise Joy Brown on July 12, 1978, near Manchester, England, was the first recorded case of in vitro fertilization (IVF)—fertilization in a laboratory dish. In the IVF procedure, the mother-to-be is given follicle-stimulating hormone (FSH) soon after menstruation, so that several secondary oocytes, rather than the typical single oocyte, will be produced (superovulation). When several follicles have reached the appropriate size, a small incision is made near the umbilicus, and the secondary oocytes are aspirated from the stimulated follicles and transferred to a solution containing sperm, where the oocytes undergo fertilization. Alternatively, an oocyte may be fertilized in vitro by suctioning a sperm or even a spermatid obtained from the testis into a tiny pipette and then injecting it into the oocyte’s cytoplasm. This procedure, termed intracytoplasmic sperm injection (ICSI), has been used when infertility is due to impairments in sperm motility or to the failure of spermatids to develop into spermatozoa. When the zygote achieved by IVF reaches the 8-cell or 16-cell stage, it is introduced into the uterus for implantation and subsequent growth.

In embryo transfer, a man’s semen is used to artificially inseminate a fertile secondary oocyte donor. After fertilization in the donor’s uterine tube, the morula or blastocyst is transferred from the donor to the infertile woman, who then carries it (and subsequently the fetus) to term. Embryo transfer is indicated for women who are infertile or who do not want to pass on their own genes because they are carriers of a serious genetic disorder.

In gamete intrafallopian transfer (GIFT) the goal is to mimic the normal process of conception by uniting sperm and secondary oocyte in the prospective mother’s uterine tubes. It is an attempt to bypass conditions in the female reproductive tract that might prevent fertilization, such as high acidity or inappropriate mucus. In this procedure, a woman is given FSH and LH to stimulate the production of several secondary oocytes, which are aspirated from the mature follicles, mixed outside the body with a solution containing sperm, and then immediately inserted into the uterine tubes.

**Congenital Defects**

An abnormality that is present at birth, and usually before, is called a congenital defect. Such defects occur during the formation of structures that develop during the period of organogenesis, the fourth
Emesis gravidarum (Em-e-sis gra-VID-ar-um; emesis — to vomit; gravida — a childbearing woman) Episodes of nausea and possibly vomiting that are most likely to occur in the morning during the early weeks of pregnancy; also called morning sickness. Its cause is unknown, but the high levels of human chorionic gonadotropin (hCG) secreted by the placenta, and of progesterone secreted by the ovaries, have been implicated. If the severity of these symptoms requires hospitalization for intravenous feeding, the condition is known as hyperemesis gravidarum.

Epigenesis (ep-i-GEN-e-sis; epi — upon; -genesis — creation) The development of an organism from an undifferentiated cell.

Fertilization age Two weeks less than the gestational age since a secondary oocyte is not fertilized until about two weeks after the last normal menstrual period (LNMP).

Fetal alcohol syndrome (FAS) A specific pattern of fetal malformation due to intrauterine exposure to alcohol. FAS is one of the most common causes of mental retardation and the most common preventable cause of birth defects in the United States.

Fetal surgery A surgical procedure performed on a fetus; in some cases the uterus is opened and the fetus is operated on directly.

Down Syndrome

Down syndrome (DS) is a disorder characterized by three, rather than two, copies of at least part of chromosome 21. Overall, one infant in 900 is born with Down syndrome. However, older women are more likely to have a DS baby. The chance of having a baby with this syndrome, which is less than 1 in 3000 for women under age 30, increases to 1 in 300 in the 35–39 age group and to 1 in 9 at age 48.

Down syndrome is characterized by mental retardation, retarded physical development (short stature and stubby fingers), distinctive facial structures (large tongue, flat profile, broad skull, slanting eyes, and round head), kidney defects, suppressed immune system, and malformations of the heart, ears, hands, and feet. Sexual maturity is rarely attained, and life expectancy is shorter.

Fetal surgery has been used to repair diaphragmatic hernias and remove lesions in the lungs.

Gestational age (jes-TA-shun-al; gestatus — to bear) The age of an embryo or fetus calculated from the presumed first day of the last normal menstrual period (LNMP).

Karyotype (KAR-e-ô-tip; karyo- — nucleus) The chromosomal characteristics of an individual presented as a systematic arrangement of pairs of metaphase chromosomes arrayed in descending order of size and according to the position of the centromere (see Figure 29.24); useful in judging whether chromosomes are normal in number and structure.

Klinefelter’s syndrome A sex chromosome aneuploidy, usually due to trisomy XXY, that occurs once in every 500 births. Such individuals are somewhat mentally disadvantaged, sterile males with undeveloped testes, scant body hair, and enlarged breasts.

Lethal gene (Lë-thal jën; lethum — death) A gene that, when expressed, results in death either in the embryonic state or shortly after birth.

Metafemale syndrome A sex chromosome aneuploidy characterized by at least three X chromosomes (XXX) that occurs about once in every 700 births. These females have underdeveloped genital organs and limited fertility, and most are mentally retarded.

Primordium (pri-MOR-de-ôm; primus — first; -ordior — to begin) The beginning or first discernible indication of the development of an organ or structure.

Puerperal fever (puér-ER-per-èl; puer — child) An infectious disease of childbirth, also called puerperal sepsis and childbed fever. The disease, which results from an infection originating in the birth canal, affects the mother’s endometrium. It may spread to other pelvic structures and lead to septicemia.

Turner’s syndrome A sex chromosome aneuploidy caused by the presence of a single X chromosome (designated XO); occurring about once in every 5000 births, it produces a sterile female with virtually no ovaries and limited development of secondary sex characteristics. Other features include short stature, webbed neck, underdeveloped breasts, and widely spaced nipples. Intelligence usually is normal.
Prenatal Diagnostic Tests (p. 1153)

1. Several prenatal diagnostic tests are used to detect genetic disorders and to assess fetal well-being. These include fetal ultrasonography, in which an image of a fetus is displayed on a screen; amniocentesis, the withdrawal and analysis of amniotic fluid and the fetal cells within it; and chorionic villi sampling (CVS), which involves withdrawal of chorionic villi tissue for chromosomal analysis.

2. CVS can be done earlier than amniocentesis, and the results are available more quickly, but it is slightly riskier than amniocentesis.

3. Noninvasive prenatal tests include the maternal alpha-fetoprotein (AFP) test to detect neural tube defects and the Quad AFP Plus test to detect Down syndrome, trisomy 18, and neural tube defects.
Maternal Changes During Pregnancy (p. 1155)
1. Pregnancy is maintained by human chorionic gonadotropin (hCG), estrogens, and progesterone.
2. Human chorionic somatomammotropin (hCS) contributes to breast development, protein anabolism, and catabolism of glucose and fatty acids.
3. Relaxin increases flexibility of the pubic symphysis and helps dilate the uterine cervix near the end of pregnancy.
4. Corticotropin-releasing hormone, produced by the placenta, is thought to establish the timing of birth, and stimulates the secretion of cortisol by the fetal adrenal gland.
5. During pregnancy, several anatomical and physiological changes occur in the mother.

Exercise and Pregnancy (p. 1158)
1. During pregnancy, some joints become less stable, and certain physical activities are more difficult to execute.
2. Moderate physical activity does not endanger the fetus in a normal pregnancy.

Labor (p. 1158)
1. Labor is the process by which the fetus is expelled from the uterus through the vagina to the outside. True labor involves dilation of the cervix, expulsion of the fetus, and delivery of the placenta.
2. Oxytocin stimulates uterine contractions via a positive feedback cycle.

Adjustments of the Infant at Birth (p. 1160)
1. The fetus depends on the mother for oxygen and nutrients, the removal of wastes, and protection.
2. Following birth, an infant’s respiratory and cardiovascular systems undergo changes to enable them to become self-supporting during postnatal life.

The Physiology of Lactation (p. 1161)
1. Lactation refers to the production and ejection of milk by the mammary glands.
2. Milk production is influenced by prolactin (PRL), estrogens, and progesterone.
3. Milk ejection is stimulated by oxytocin.

4. A few of the many benefits of breast-feeding include ideal nutrition for the infant, protection from disease, and decreased likelihood of developing allergies.

Inheritance (p. 1163)
1. Inheritance is the passage of hereditary traits from one generation to the next.
2. The genetic makeup of an organism is called its genotype; the traits expressed are called its phenotype.
3. Dominant genes control a particular trait; expression of recessive genes is masked by dominant genes.
4. Many patterns of inheritance do not conform to the simple dominant–recessive patterns.
5. In incomplete dominance, neither member of an allelic pair dominates; phenotypically, the heterozygote is intermediate between the homozygous dominant and the homozygous recessive.
6. In multiple-allele inheritance, genes have more than two alternative forms. An example is the inheritance of ABO blood groups.
7. In complex inheritance, a trait such as skin or eye color is controlled by the combined effects of two or more genes and may be influenced by environmental factors.
8. Each somatic cell has 46 chromosomes—22 pairs of autosomes and 1 pair of sex chromosomes.
9. In females, the sex chromosomes are two X chromosomes; in males, they are one X chromosome and a much smaller Y chromosome, which normally includes the prime male-determining gene, called SRY.
10. If the SRY gene is present and functional in a fertilized ovum, the fetus will develop testes and differentiate into a male. In the absence of SRY, the fetus will develop ovaries and differentiate into a female.
11. Red–green color blindness and hemophilia result from recessive genes located on the X chromosome. These sex-linked traits occur primarily in males because of the absence of any counterbalancing dominant genes on the Y chromosome.
12. A mechanism termed X-chromosome inactivation (lyonization) balances the difference in number of X chromosomes between males (one X) and females (two Xs). In each cell of a female’s body, one X chromosome is randomly and permanently inactivated early in development and becomes a Barr body.
13. A given phenotype is the result of the interactions of genotype and the environment.

SELF-QUIZ QUESTIONS

Fill in the blanks in the following statements.
1. The three stages of true labor, in order of occurrence, are _____, _____, and _____.
2. Hormones produced by the _____ are responsible for maintaining the pregnancy during the first 3–4 months. The hormone responsible for preventing degeneration of the corpus luteum is _____ produced by the trophoblast.
3. Indicate the germ layers responsible for development of the following structures: (a) muscle, bone, and peritoneum: _____; (b) nervous system and epidermis: _____; (c) epithelial linings of respiratory and gastrointestinal tracts: _____.

Indicate whether the following statement is true or false.
4. Labor is an example of a negative feedback cycle that ends with the birth of the infant.
Choose the one best answer to the following questions.

5. Which of the following are true? (1) During implantation the outer cell mass of the blastocyst orients toward the endometrium. (2) The decidua basalis provides glycogen and lipids for the developing fetus. (3) The decidua parietalis becomes the maternal part of the placenta. (4) During implantation, the syncytiotrophoblast secretes enzymes that allow the blastocyst to penetrate the uterine lining. (5) After fetal delivery, the decidua separates from the endometrium and is released from the uterus.
   (a) 2, 4, and 5 (b) 1, 2, and 3 (c) 2, 3, 4, and 5 (d) 1, 2, 3, 4, and 5 (e) 1, 3, and 5

6. Which of the following are maternal changes that occur during pregnancy? (1) altered pulmonary function; (2) increased stroke volume, cardiac output, and heart rate, and decreased blood volume; (3) weight gain; (4) increased gastric motility, causing a delay in gastric emptying time; (5) edema and possible varicose veins.
   (a) 1, 2, 3, and 4 (b) 2, 3, 4, and 5 (c) 1, 3, 4, and 5 (d) 1, 3, and 5 (e) 2, 4, and 5

7. Which of the following statements is correct? (a) Normal traits always dominate over abnormal traits. (b) Occasionally an error in meiosis called nondisjunction results in an abnormal number of chromosomes. (c) The mother always determines the sex of the child because she has either an X or Y gene in her oocytes. (d) Most patterns of inheritance are simple dominant-recessive inheritances. (e) Genes are expressed normally regardless of any outside influence such as chemicals or radiation.

8. Which of the following are true concerning fertilization? (1) The sperm first penetrate the zona pellucida and then the corona radiata. (2) The binding of specific membrane proteins in the sperm head to ZP3 causes the release of acrosomal contents. (3) Sperm are able to fertilize the oocyte within minutes after ejaculation. (4) Depolarization of the cell membrane of the secondary oocyte inhibits fertilization by more than one sperm. (5) The oocyte completes meiosis II after fertilization.
   (a) 1, 2, 4, and 5 (b) 1, 3, and 5 (c) 1, 2, 3, and 4 (d) 1, 4, and 5 (e) 2, 4, and 5

9. Amniotic fluid (1) is derived entirely from a filtrate of maternal blood, (2) acts as a fetal shock absorber, (3) provides nutrients to the fetus, (4) helps regulate fetal body temperature, (5) prevents adhesions between the skin of the fetus and surrounding tissues.
   (a) 1, 2, 3, 4, and 5 (b) 2, 4, and 5 (c) 2, 3, 4, and 5 (d) 1, 4, and 5 (e) 1, 2, 4, and 5

10. Which of the following structures develop during the fourth week after fertilization? (1) embryonic folding, (2) the neural tube, (3) otic placode (beginning of the ear), (4) beginning of the eyes, (5) upper and lower limb buds.
    (a) 1 and 2 (b) 1, 2, and 5 (c) 1, 2, 3, 4, and 5 (d) 2, 3, and 5 (e) 1, 3, 4, and 5

11. Match the following:
    — (a) a fluid-filled sphere of cells that enters the uterine cavity
    — (b) cells produced by cleavage
    — (c) the developing individual from week nine of pregnancy until birth
    — (d) the outer covering of cells of the blastocyst
    — (e) membrane derived from trophoblast
    — (f) early divisions of the zygote
    — (g) a solid sphere of cells still surrounded by the zona pellucida
    — (h) event in which differentiation into the three primary germ layers occurs
    — (i) embryonic development of structures that will become the nervous system
    — (j) the formation of blood vessels to support the developing embryo
    — (k) result of the fusion of female and male pronuclei
    (1) cleavage (2) blastomeres (3) morula (4) angiogenesis (5) trophoblast (6) blastocyst (7) zygote (8) gastrulation (9) neurulation (10) chorion (11) fetus

12. Match the following:
    — (a) stimulates the corpus luteum to continue production of progesterone and estrogens
    — (b) increases the flexibility of the pubic symphysis and helps dilate the uterine cervix during labor
    — (c) secreted by the placenta; helps establish the timing of birth and increases the secretion of cortisol for fetal lung maturation
    — (d) helps prepare mammary glands for lactation; regulates certain aspects of maternal and fetal metabolism
    — (e) stimulates uterine contractions; responsible for the milk ejection reflex
    — (f) promotes milk synthesis and secretion; inhibited by progesterone during pregnancy
    (1) oxytocin (2) human chorionic somatomammotropin (3) human chorionic gonadotropin (4) prolactin (5) corticotropin-releasing hormone (6) relaxin
13. Match the following:

(a) the penetration of a secondary oocyte by a single sperm cell
(b) fertilization of a secondary oocyte by more than one sperm
(c) the attachment of a blastocyst to the endometrium
(d) the fusion of the genetic material from a haploid sperm and a haploid secondary oocyte into a single diploid nucleus
(e) the induction by the female reproductive tract of functional changes in sperm that allow them to fertilize a secondary oocyte
(f) the examination of embryonic or fetal cells sloughed off into the amniotic fluid
(g) an abnormal condition of pregnancy characterized by sudden hypertension, large amounts of protein in urine, and generalized edema
(h) noninvasive test that can detect fetal neural tube defects
(i) the process of giving birth
(j) the period of time (about 6 weeks) during which the maternal reproductive organs and physiology return to the prepregnancy state

14. Match the following:

(a) the control of inherited traits by the combined effects of many genes
(b) the two alternative forms of a gene that code for the same trait and are at the same location on homologous chromosomes
(c) abnormal number of chromosomes due to failure of homologous chromosomes or chromatids to separate
(d) inheritance based on genes that have more than two alternative forms; an example is the inheritance of blood type
(e) a cell in which one or more chromosomes of a set is added or deleted
(f) refers to an individual with different alleles on homologous chromosomes
(g) traits linked to the X chromosome
(h) permanent inheritable change in an allele that produces a different variant of the same trait
(i) neither member of the allelic pair is dominant over the other, and the heterozygote has a phenotype intermediate between the homozygous dominant and the homozygous recessive
(j) refers to how the genetic makeup is expressed in the body; the physical or outward expression of a gene
(k) a homozygous dominant, homozygous recessive, or heterozygous genetic makeup; the actual gene arrangement
(l) refers to a person with the same alleles on homologous chromosomes
(m) inactivated X chromosome in females
(n) heterozygous individuals who possess a recessive gene (but do not express it) and can pass the gene on to their offspring
(o) interchange of portions of nonhomologous chromosomes
(p) an allele that masks the presence of another allele and is fully expressed
1174 CHAPTER 29 • DEVELOPMENT AND INHERITANCE

15. Match the following:

(a) the embryonic membrane that entirely surrounds the embryo
   (1) decidua

(b) functions as an early site of blood formation; contains cells that migrate into the gonads and
differentiate into the primitive germ cells
   (2) placenta

(c) becomes the principal part of the embryonic placenta; produces human chorionic gonadotropin
   (3) amnion

(d) modified endometrium after implantation has occurred; separates from the endometrium after the
   fetus is delivered
   (4) chorion

(e) contains the vascular connections between mother and fetus
   (5) allantois

(f) the fetal portion is formed by the chorionic villi and the maternal portion is formed by the decidua
   basalis of the endometrium; allows oxygen and nutrients to diffuse from maternal blood into fetal
   blood
   (6) yolk sac

(g) serves as an early site of blood vessel formation
   (7) notochord

(h) finger-like projections of the chorion that bring maternal and fetal blood vessels into close proximity
   (8) chorionic villi

(i) plays an important role in induction whereby an inducing tissue stimulates the development of an
   unspecialized responding tissue into a specialized tissue
   (9) umbilical cord

CRITICAL THINKING QUESTIONS

1. Kathy is breast-feeding her infant and is experiencing what feels like early labor pains. What is causing these painful feelings? Is there a benefit to them?

2. Jack has hemophilia, which is a sex-linked blood clotting disorder. He blames his father for passing on the gene for hemophilia. Explain to Jack why his reasoning is wrong. How can Jack have hemophilia if his parents do not?

3. Alisa has asked her obstetrician to save and freeze her baby's cord blood after delivery in case the child needs a future bone marrow transplant. What is in the baby's cord blood that could be used to treat future disorders in the child?

ANSWERS TO FIGURE QUESTIONS

29.1 Capacitation is the group of functional changes in sperm that enable them to fertilize a secondary oocyte, which occur after they have been deposited in the female reproductive tract.

29.2 A morula is a solid ball of cells; a blastocyst consists of a rim of cells (trophoblast) surrounding a cavity (blastocyst cavity) and an inner cell mass.

29.3 The blastocyst secretes digestive enzymes that eat away the endometrial lining at the site of implantation.

29.4 The decidua basalis helps form the maternal part of the placenta.

29.5 Implantation occurs during the secretory phase of the uterine cycle.

29.6 The bilaminar embryonic disc is attached to the trophoblast by the connecting stalk.

29.7 Gastrulation converts a bilaminar embryonic disc into a trilaminar embryonic disc.

29.8 The notochord induces mesodermal cells to develop into vertebral bodies and forms the nucleus pulposus of intervertebral discs.

29.9 The neural tube forms the brain and spinal cord; somites develop into skeletal muscles, connective tissue, and the vertebrae.

29.10 Chorionic villi help to bring the fetal and maternal blood vessels into close proximity.

29.11 The placenta participates in the exchange of materials between fetus and mother, serves as a protective barrier against many microbes, and stores nutrients.

29.12 As a result of embryonic folding, the embryo curves into a C-shape, various organs are brought into their eventual adult positions, and the primitive gut is formed.

29.13 Pharyngeal arches, clefts, and pouches give rise to structures of the head and neck.

29.14 Fetal weight doubles between the mid-fetal period and birth.

29.15 Amniocentesis is used primarily to detect genetic disorders, but it also provides information concerning the maturity (and survivability) of the fetus.

29.16 Early pregnancy tests detect elevated levels of human chorionic gonadotropin (hCG).

29.17 Relaxin increases the flexibility of the pubic symphysis and helps dilate the cervix of the uterus to ease delivery.

29.18 Complete dilation of the cervix marks the onset of the stage of expulsion.

29.19 Oxytocin also stimulates contraction of the uterus during delivery of a baby.

29.20 The odds that a child will have PKU are the same for each child—25%.

29.21 In incomplete dominance, neither member of an allelic pair is dominant; the heterozygote has a phenotype intermediate between the homozygous dominant and the homozygous recessive phenotypes.

29.22 A baby can have blood type O if each parent is heterozygous and has one i allele.

29.23 Hair color, height, and body build, among others, are traits passed on by complex inheritance.

29.24 The female sex chromosomes are XX, and the male sex chromosomes are XY.

29.25 The chromosomes that are not sex chromosomes are called autosomes.

29.26 A red-green color-blind female has an X’X’ genotype.

The periodic table lists the known chemical elements, the basic units of matter. The elements in the table are arranged left-to-right in rows in order of their atomic number, the number of protons in the nucleus. Each horizontal row, numbered from 1 to 7, is a period. All elements in a given period have the same number of electron shells as their period number. For example, an atom of hydrogen or helium each has one electron shell, while an atom of potassium or calcium each has four electron shells. The elements in each column, or group, share chemical properties. For example, the elements in column IA are very chemically reactive, whereas the elements in column VIIA have full electron shells and thus are chemically inert.

Scientists now recognize 117 different elements; 92 occur naturally on Earth, and the rest are produced from the natural elements using particle accelerators or nuclear reactors. Elements are designated by chemical symbols, which are the first or two letters of the element's name in English, Latin, or another language.

Twenty-six of the 92 naturally occurring elements normally are present in your body. Of these, just four elements—oxygen (O), carbon (C), hydrogen (H), and nitrogen (N)—contribute about 96% of the body's mass. Eight others—calcium (Ca), phosphorus (P), potassium (K), sulfur (S), sodium (Na), chlorine (Cl), magnesium (Mg), and iron (Fe)—contribute 3.8% of the body's mass. An additional 14 elements, called trace elements because they are present in tiny amounts, account for the remaining 0.2% of the body's mass. The trace elements are aluminum, boron, chromium, cobalt, copper, fluorine, iodine, manganese, molybdenum, selenium, silicon, tin, vanadium, and zinc (coded yellow). Table 2.1 on page 29 provides information about the main chemical elements in the body.
The system of international (SI) units (Système Internationale d’Unités) is used in most countries and in many medical and scientific journals. Clinical laboratories in the United States, by contrast, usually report values for blood and urine tests in conventional units. The laboratory values in this Appendix give conventional units first, followed by SI equivalents in parentheses. Values listed for various blood tests should be viewed as reference values rather than absolute “normal” values for all well people. Values may vary due to age, gender, diet, and environment of the subject or the equipment, methods, and standards of the lab performing the measurement.

Chapter 29  

Answers to Critical Thinking Questions

Chapter 1  
1. No. Computed tomography is used to look at differences in tissue density. To assess activity in an organ such as the brain, a positron emission tomography (PET) scan or a single-photo-emission computerized tomography (SPECT) scan would both provide a colorized visual assessment of brain activity.

Chapter 2  
1. Neither butter nor margarine are particularly good choices for frying eggs. Butter contains saturated fats that are associated with heart disease. However, many margarines contain hydrogenated or partially hydrogenated trans-fatty acids that also increase the risk of heart disease. An alternative would be frying the eggs in any of the mono- or polyunsaturated fats such as olive oil, peanut oil, or corn oil.

Chapter 3  
1. Synthesis of mucin by ribosomes on rough endoplasmic reticulum, to transport vesicle, to entry face of Golgi complex, to transfer vesicle, to medial cisternae where protein is modified, to transfer vesicle, to exit face, to secrete vesicle, to plasma membrane where it undergoes exocytosis.

Chapter 4  
1. Since smooth ER inactivates or detoxifies drugs, and peroxisomes also destroy harmful substances such as alcohol, we would expect to see increased temperature can cause denaturing of structural proteins and vital enzymes. When this happens, the proteins become nonfunctional. If the denatured enzymes are required for reactions that are necessary for life, then the infant could die.

Chapter 5  
1. Simply adding water to the table sugar does not cause it to break apart into monosaccharides. The water acts as a solvent, dissolving the sucrose, and forming a sugar-water solution. To complete the breakdown of table sugar to glucose and fructose would require the presence of the enzyme sucrase.
cause weight loss, it also can result in a lack of absorption of essential vitamins and minerals; dietary supplements are generally required.

In order to restore water balance to the cells, the runners need to consume hypotonic solutions. The water in the hypotonic solution will move from the blood, into the interstitial fluid, and then into the cells. Plain water works well; sports drinks contain water and some electrolytes (which may have been lost due to sweating) but will still be hypotonic in relation to the body cells.

Chapter 4

1. There are many possible adaptations, including: more adipose tissue for insulation; thicker bones for support; more red blood cells for oxygen transport; increased thickness of skin to prevent water loss; etc.

2. Infants tend to have a high proportion of brown fat, which contains many mitochondria and is highly vascularized. When broken down, brown fat produces heat that helps to maintain infants’ body temperatures. This heat can also warm the blood, which then distributes the heat throughout the body.

3. Your bread-and-water diet is not providing you with the necessary nutrients to encourage tissue repair. You need proper amounts of many essential vitamins, especially vitamin C, which is required for repair of the matrix and blood vessels. Vitamin A is needed to help properly maintain epithelial tissue. Adequate protein is also needed in order to synthesize the structural proteins of the damaged tissue.

Chapter 5

1. The dust particles are primarily keratinocytes that are shed from the stratum corneum of the skin.

2. Tattoos are created by depositing ink into the dermis, which does not undergo shedding as the epidermis does. Although the tattoo will fade due to exposure to sunlight and the flushing away of ink particles by the lymphatic system, the tattoo is indeed permanent.

3. Chef Eduardo has damaged the nail matrix—the part of the nail that produces growth. Because the damaged area has not regrown properly, the nail matrix may be permanently damaged.

Chapter 6

1. Due to the strenuous, repetitive activity, Taryn has probably developed a stress fracture of her right tibia (lower leg bone). Stress fractures are due to repeated stress on a bone that causes microscopic breaks in the bone without any evidence of injury to other tissue. An x-ray would not reveal the stress fracture, but a bone scan would. Thus the bone scan would either confirm or negate the physician’s diagnosis.

2. When Marcus broke his arm as a child, he injured his epiphyseal (growth) plate. Damage to the cartilage in the epiphyseal plate resulted in premature closure of the plate, which interfered with the lengthwise growth of the arm bone.

3. Exercise causes mechanical stress on bones, but because there is effectively zero gravity in space, the pull of gravity on bones is missing. The lack of stress from gravity results in bone demineralization and weakness.

Chapter 7

1. Inability to open mouth—damage to the mandible, probably at temporomandibular joint; black eye—trauma to the ridge over the supraorbital margin; broken nose—probably damage to the nasal septum (includes the vomer, septal cartilage, and perpendicular plate of the ethmoid) and possibly the nasal bones; broken cheek—fracture of zygomatic bone; broken upper jaw—fracture of maxilla; damaged eye socket—fracture of parts of the sphenoid, frontal, ethmoid, palatine, zygomatic, lacrimal and maxilla (all compose the eye socket); punctured lung—damage to the thoracic vertebrae, which have punctured the lung.

2. Due to the repeated and extensive tension on his bone surfaces, Bubba would experience deposition of new bone tissue. His arm bones would be thicker and with increased raised areas (projections) where the tendons attach his muscles to bone.

3. The “soft area” being referred to is the anterior fontanel, located between the parietal and frontal bones. This is one of several areas of fibrous connective tissue in the skull that has not ossified; it should complete its ossification at 18–24 months after birth. Fontanels allow flexibility of the skull for childbirth and for brain growth after birth. The connective tissue will not allow passage of water; thus no brain damage will occur through simply washing the baby’s hair.

Chapter 8

1. There are several characteristics of the bony pelvis that can be used to differentiate male from female: (1) The pelvis in the female is wider and more shallow that the male’s; (2) the pelvic brim of the female is larger and more oval; (3) the pubic arch has an angle greater than 90°; (4) the pelvic outlet is wider than in a male’s; (5) the female’s iliac crest is less curved and the ilium less vertical. Table 8.1 provides additional differences between female and male pelvises. Age of the skeleton can be determined by the size of the bones, the presence or absence of epiphyseal plates, the degree of demineralization of the bones, and the general appearance of the “bumps” and ridges of bone.

2. Infants do have “flat feet” because their arches have not yet developed. As they begin to stand and walk, the arches should begin to develop in order to accommodate and support their body weight. The arches are usually fully developed by age 12 or 13, so Dad doesn’t need to worry yet!

3. There are 14 phalanges in each hand: two bones in the thumb and three in each of the other fingers. Farmer White has lost five phalanges on his left hand (two in his thumb and three in his index finger), so he has nine remaining on his left and 14 remaining on his right for a total of 23.

Chapter 9

1. Katie’s vertebral column, head, thighs, lower legs, lower arms, and fingers are flexed. Her lower arms and shoulders are medially rotated. Her thighs and arms are adducted.

2. The knee joint is commonly injured, especially among athletes. The twisting of Jeremiah’s leg could have resulted in a multitude of internal injuries to the knee joint but often football players suffer tearing of the anterior cruciate ligament and medial meniscus. The immediate swelling is due to blood from damaged blood vessels, damaged synovial membranes, and the torn meniscus. Continued swelling is a result of a buildup of synovial fluid, which can result in pain and decreased mobility. Jeremiah’s doctor may aspirate some of the fluid (“draining the water off his knee”) and might want to perform arthroscopy to check for the extent of the knee damage.

3. The condylar processes of the mandible passed anteriorly to the articular tubercles of the temporal bones and this dislocated Antonio’s mandible. It could be corrected by pressing the thumbs downward on the lower molar teeth and pushing the mandible backward.

Chapter 10

1. Muscle cells lose their ability to undergo cell division after birth. Therefore, the increase in size is not due to an increase in the number of muscle cells but rather is due to enlargement of the existing muscle fibers (hypertrophy). This enlargement can occur from forceful, repetitive muscular activity. It will cause the muscle fibers to increase their production of internal structures such as mitochondria and myofibrils and produce an increase in the muscle fiber diameter.

2. The “dark meat” of both chickens and ducks is composed primarily of slow oxidative (SO) muscle fibers. These fibers contain large amounts of myoglobin and capillaries, which accounts for their dark color. In addition, these fibers contain large numbers of mitochondria and generate ATP by aerobic respiration. SO fibers are resistant to fatigue and can produce sustained contractions for many hours. The legs of chickens and ducks are used for support, walking, and swimming (in ducks), all activities in which endurance is needed. In addition, migrating ducks require SO fibers in their breasts to enable them to have enough energy to fly for extremely long distances while migrating. There may be some fast oxidative-glycolytic (FOG) fibers in the dark meat. FOG fibers also contain large amounts of myoglobin and capillaries, contributing to the dark color. They can use aerobic or anaerobic cellular respiration to generate ATP and have high-to-moderate resistance to fatigue. These fibers would be good for the occasional “sprint” that ducks and chickens undergo to escape dangerous situations. In contrast, the white meat of a chicken breast is composed primarily of fast glycolytic (FG) fibers. FG fibers have lower amounts of myoglobin and capillaries that give the meat its white color. There are also few mitochondria in FG fibers so these fibers generate ATP mainly by glycolysis.
These fibers contract strongly and quickly and are adapted for intense anaerobic movements of short duration. Chickens occasionally use their breasts for flying extremely short distances, usually to escape prey or perceived danger, so PG fibers are appropriate for their breast muscle.

3. Destruction of the somatic motor neurons to skeletal muscle fibers will result in a loss of stimulation to the skeletal muscles. When not stimulated on a regular basis, a muscle begins to lose its muscle tone. Through lack of use, the muscle fibers will weaken, begin to decrease in size, and can be replaced by fibrous connective tissue, resulting in a type of denervation atrophy. A lack of stimulation of the breathing muscles (especially the diaphragm) from motor neurons can result in inability of the breathing muscles to contract, thus causing respiratory paralysis and possibly death of the individual from respiratory failure.

Chapter 11
1. All of the following could occur on the affected (right) side of the face: (1) drooping of eyelid—levator palpebrae superioris; (2) drooping of the mouth, drooling, keeping food in mouth—orbicularis oris, buccinator; (3) uneven smile—zygomaticus major, levator labii superioris, risorius; (4) unable to wrinkle forehead—occipitofrontalis; (5) trouble sucking through a straw—buccinator.

2. Baboscoposus, external urethral sphincter, and deep transverse perineal.

3. The rotator cuff is formed by a combination of the tendons of four deep muscles of the shoulder—supraspinatus, infraspinatus, subscapularis, and teres minor. These muscles add strength and stability to the shoulder joint. Although any of the muscles’ tendons can be injured, the subscapularis is most often damaged. Dependent upon the injured muscle, Jose may have trouble medially rotating his arm (subscapularis), abducting his arm (supraspinatus), laterally rotating his arm (infraspinatus, teres minor), adducting his arm (infraspinatus, teres minor), or extending his arm (teres minor).

Chapter 12
1. Smelling the coffee and hearing the alarm are somatic sensory, stretching and yawning are somatic motor, salivating is autonomic (parasympathetic) motor, stomach rumble is enteric motor.

2. Demyelination or destruction of the myelin sheath can lead to multiple problems, especially in infants and children whose myelin sheaths are still in the process of developing. The affected axons deteriorate, which will interfere with function in both the CNS and PNS. There will be lack of sensation and loss of motor control with less rapid and less coordinated body responses. Damage to the axons in the CNS can be permanent and Ming’s brain development may be irreversibly affected.

3. Dr. Moro could develop a drug that: (1) is an agonist of substance P; (2) blocks the breakdown of substance P; (3) blocks the reuptake of substance P; (4) promotes the release of substance P; (5) suppresses the release of enkephalins.

Chapter 13
1. The needles will pierce the epidermis, dermis, and subcutaneous layer and then go between the vertebrae through the epidural space, the dura mater, the subdural space, the arachnoid mater, and into the CSF in the subarchnoid space. CSF is produced in the brain, and the spinal meninges are continuous with the cranial meninges.

2. The anterior gray horns contain cell bodies of somatic motor neurons and motor nuclei that are responsible for the nerve impulses for skeletal muscle contraction. Because the lower cervical region is affected (brachial plexus, C5–C8), you would expect that Sunil may have trouble with movement in his shoulder, arm, and hand on the affected side.

3. Allyson has damaged her posterior columns in the lower (lumbar) region of the spinal cord. The posterior columns are responsible for transmitting nerve impulses responsible for awareness of muscle position (proprioception) and touch—which are affected in Allyson—as well as other functions such as light pressure sensations, and vibration sensations.

Chapter 14
1. Movement of the right arm is controlled by the left hemisphere’s primary motor area, located in the precentral gyrus. Speech is controlled by Broca’s area in the left hemisphere’s frontal lobe just superior to the lateral cerebral sulcus.
odorants. The facial nerve also serves taste buds in the anterior two-thirds of the tongue, so damage can affect taste sensations. Hearing will be affected by a damaged facial nerve because the stapedius muscle, which is attached to the staples, is innervated by the facial nerve. Contraction of the stapedius muscle helps to protect the inner ear from prolonged loud noises. Damage to the facial nerve will result in sounds that are excessively loud, resulting in more susceptibility to damage by prolonged loud noises.

2. With age, Gertrude has lost much of her sense of smell and taste due to a decline in olfactory and gustatory receptors. Since smell and taste are intimately linked, food no longer smells nor tastes as good to Gertrude. Gertrude has presbyopia, a loss of lens elasticity, which makes it difficult to read. She may also be experiencing age-related loss of sharpness of vision and depth perception. Gertrude’s hearing difficulties could be a result of damage to hair cells in the organ of Corti or degeneration of the nerve pathway for hearing. The “buzzing” Gertrude hears may be tinnitus, which also occurs more frequently in the elderly.

3. Some of the eyedrops placed in the eye may pass through the nasolacrimal duct into the nasal cavity where olfactory receptors are stimulated. Because most “tastes” are actually smells, the child will “taste” the medicine from her eye.

Chapter 18
1. Yes, Amanda should visit the clinic, as these are serious signs and symptoms. She has an enlarged thyroid gland, or goiter. The goiter is probably due to hypothyroidism, which is causing the weight gain, fatigue, mental dullness, and other symptoms.

2. Amanda’s problem is her pituitary gland, which is not secreting normal levels of TSH. Rising thyroxine (T4) levels after the TSH injection indicates that her thyroid is functioning normally and able to respond to the increased TSH levels. If the thyroxine levels had not risen, then the problem would have been her thyroid gland.

3. Mr. Hernandez has diabetes insipidus caused by either insufficient production or release of ADH due to hypothalamic or posterior pituitary damage. ADH is produced in the hypothalamus and released by the posterior pituitary gland. The deficiency results in increased thirst, but with no glucose or ketones present in the urine (which would indicate diabetes mellitus). The symptoms are due to insufficient ADH due to hypothalamic or posterior pituitary damage, which affects the production or release of ADH. ADH helps the kidneys conserve water by reabsorbing water from the urine back into the body. Without ADH, the kidneys cannot conserve water, and the person experiences increased thirst due to the leakage of large amounts of urine. Additionally, the kidneys cannot reabsorb enough water to maintain normal blood pressure, which can lead to symptoms of dehydration and low blood pressure.

Chapter 19
1. The broad spectrum antibiotics may have destroyed the bacteria that caused Shilpa’s bladder infection but also destroyed the naturally occurring large intestine bacteria that produce vitamin K. Vitamin K is required for the synthesis of four clotting factors (II, VII, IX, and X). Without these clotting factors present in normal amounts, Shilpa will experience clotting problems until her liver is functioning normally and able to respond to the increased TSH levels. If the thyroxine levels had not risen, then the problem would have been her thyroid gland.

2. Mrs. Brown’s kidney failure is interfering with her ability to produce erythropoietin (EPO). Her physician can prescribe Epoetin alfa, a recombinant EPO, which is very effective in treating the decline in RBC production with renal failure.

3. A primary problem Thomas may experience is with clotting. Clotting time becomes longer because the liver is responsible for producing many of the clotting factors and clotting proteins such as fibrinogen. Thrombopoietin, which is very effective in treating the decline in RBC production with renal failure.

Chapter 20
1. The dental procedures introduced bacteria into Gerald’s blood. The bacteria colonized his endocardium and heart valves, resulting in bacterial endocarditis. Gerald may have had a previously undetected heart murmur, or the heart murmur may have resulted from his endocarditis. His physician will want to monitor his heart to watch for further damage to the valve.

2. Extremely rapid heart rates can result in a decreased stroke volume due to insufficient ventricular filling. As a result, the cardiac output will decline to the point where there may not be enough blood reaching the central nervous system. She initially may experience light-headedness but could lose consciousness if the cardiac output declines dramatically.

3. Mr. Perkins is suffering from angina pectoris and has several risk factors for coronary artery disease such as smoking, obesity, sedentary lifestyle, and male gender. Cardiac angiography involves the use of a cardiac catheter to inject a radiopaque medium into the heart and its vessels. The angiogram may reveal blockages such as atherosclerotic plaques in his coronary arteries.

Chapter 21
1. The hole in the heart was the foramen ovale, which is an opening between the right and left atria. In fetal circulation it allows blood to bypass the right ventricle, enter the left atrium and join systemic circulation. The “hole” should close shortly after birth to become the fossa ovalis. Closure of the foramen ovale after birth will allow the deoxygenated blood from the right atrium to enter pulmonary circulation so that the blood can become oxygenated prior to entering systemic circulation. If closure doesn’t occur, surgery may be required.

2. Michael is suffering from hypovolemic shock due to the loss of blood. The low blood pressure is a result of low blood volume and a subsequent decrease in cardiac output. His rapid, weak pulse is an attempt of the heart to compensate for the decrease in cardiac output through sympathetic stimulation of the heart and increased blood levels of epinephrine and norepinephrine. His pale, cool, and clammy skin is a result of sympathetic constriction of the blood vessels of the skin and sympathetic stimulation of sweat glands. The lack of urine production is due to increased secretion of aldosterone and ADH, both of which are produced to increase blood volume in order to compensate for Michael’s hypotension. The fluid loss from his bleeding results in activation of the thirst center in the hypothalamus. His confusion and disorientation is caused by a reduced oxygen supply to the brain from the decreased cardiac output.

3. Maureen has varicose veins, a condition in which the venous valves become leaky. The leaking valves allow the backflow of blood and an increased pressure that distends the veins and allows fluid to leak into the surrounding tissue. Standing on hard surfaces for long periods of time can cause varicosities to develop. Maureen needs to elevate her legs when possible to counteract the effects of gravity on the blood flow in the lower legs. She could also utilize support hose, which adds external support for the superficial veins, much like skeletal muscle does for deeper veins. If the varices become severe, Maureen may require more extensive treatment such as sclerotherapy, radiofrequency endovenous occlusion, laser occlusion, or stripping.

Chapter 22
1. The influenza vaccination introduces a weakened or killed virus (which will not cause the disease) to the body. The immune system recognizes the antigen and mounts a primary immune response. Upon exposure to the same flu virus that was in the vaccine, the body will produce a secondary response, which will usually prevent a case of the flu. This is artificially acquired active immunity.

2. Mrs. Franco’s lymph nodes were removed because metastasis of cancerous cells can occur through the lymph nodes and lymphatic vessels. Mrs. Franco’s swelling is a lymphedema that is occurring due to the buildup of interstitial fluid from interference with drainage in the lymph vessels.

3. Tariq’s physician would need to perform an antibody titer, which is a measure of the amount of antibody in the serum. If Tariq has previously been exposed to mumps (or been vaccinated for mumps), his blood should have elevated levels of IgG antibodies after this exposure from his sister. His immune system would be experiencing a secondary response. If he has not previously had mumps and has contracted mumps from his sister, his immune system would initiate a primary response. In that case, his blood would show an elevated titer of IgM antibodies, which are secreted by plasma cells after an initial exposure to the mumps antigen.

Chapter 23
1. Aretha’s excess mucus production is causing blockage of the paranasal sinuses, which are used as hollow resonating chambers for singing and speech. In addition, her sore throat could be due to inflammation of the pharynx and larynx, which will affect their normal functions. Normally, the pharynx also acts as a resonating chamber and the true vocal cords, located in the larynx, vibrate for speech and singing. Inflammation of the true vocal cords (laryngitis) interferes with their ability to freely vibrate, which will affect both singing and speech.
2. In emphysema, there is destruction of the alveolar walls, producing abnormally large air spaces that remain filled with air during exhalation. The destruction of alveoli decreases the surface area for gas exchange across the respiratory membrane, resulting in a decreased blood O₂ level. Damage to the alveolar walls also causes a loss of elasticity, making exhalation more difficult. This can result in a buildup of CO₂. Emphysema causes constriction of bronchioles. This narrowing of the breathing airways increases resistance and results in more pressure required to maintain airflow. Cigarette smoke contains nicotine, carbon monoxide, and a variety of irritants, all of which affect the lungs. Nicotine constricts terminal bronchioles, decreasing the air flow into and out of the lungs; carbon monoxide binds to hemoglobin, reducing its ability to carry oxygen; irritants such as tar and fine particulate matter destroy cilia and increase mucus secretion, interfering with the ability of the respiratory passages to cleanse themselves.

3. The squirrel's nest blocked the passage of exhaust gas from the furnace, causing an accumulation of carbon monoxide (CO), a colorless, odorless gas, in the home. As they were sleeping, their blood was saturated with CO, which has a stronger affinity for hemoglobin than oxygen. As a result, the Robinsons became oxygen deficient. Without adequate oxygenation of the brain, the Robinsons died during their sleep.

Chapter 24
1. HCl has several important roles in digestion. HCl stimulates the secretion of hormones that promote the flow of bile and pancreatic juice. The presence of HCl destroys certain microbes that may have been ingested with food. HCl begins denaturing proteins in food, and provides the proper chemical environment for activating pepsinogen into pepsin, which breaks apart certain peptide bonds in proteins. It also helps in the action of gastric lipase, which splits triglycerides into free fatty acids and monoglycerides.
2. Blockage of the pancreatic and bile ducts prevent pancreatic digestive enzymes and bile from reaching the duodenum. As a consequence, there will be problems digesting carbohydrates, proteins, nucleic acids, and lipids. Of particular concern is lipid digestion since the pancreatic juices contain the primary lipid-digesting enzyme. Fats will not be adequately digested, and Trey's feces will contain larger than normal amounts of lipids. In addition, the lack of bile salts will affect the body's ability to emulsify lipids and to form micelles required for absorption of fatty acids and monoglycerides (from lipid breakdown). When lipids are not absorbed properly, there will be malabsorption of the lipid-soluble vitamins (A, D, E, and K).
3. Antonio experienced gastroesophageal reflux. The stomach contents backed up (refluxed) into Antonio's esophagus due to a failure of the lower esophageal sphincter to close. The HCl from the stomach irritated the esophageal wall, which resulted in the burning sensation he felt; this is commonly known as "heartburn," even though it is not related to the heart. Antonio's recent meal worsened the problem. Alcohol and smoking both can cause the sphincter to relax, while certain foods such as tomatoes, chocolate, and coffee can stimulate stomach acid secretion. In addition, lying down immediately after a meal can exacerbate the problem.

Chapter 25
1. Ingestion of cyanide affects cellular respiration. The cyanide binds to the cytochrome oxidase complex in the inner membrane of mitochondria. Blocking this complex interferes with the last step in electron transport in aerobic ATP production. Jane Doe's body would quickly run out of energy to perform vital functions, resulting in her death.
2. Glenn's total cholesterol and LDL levels are high, while his HDL levels are low. Total cholesterol above 239mg/dL and LDL above 159mg/dL are considered high. The ratio of total cholesterol (TC) to HDL-cholesterol is a predictor of the risk of developing coronary artery disease. Glenn's TC to HDL is 15; a ratio above 4 is undesirable. His ratio places him at high risk of developing coronary artery disease. In addition, for every 50mg/dL TC over 200mg/dL, the risk of a heart attack doubles. Glenn needs to reduce his TC and LDL-cholesterol while raising his HDL-cholesterol levels. LDLs contribute to fatty plaque formation on coronary artery walls. On the other hand, HDLs help remove excess cholesterol from the blood, which helps decrease the risk of coronary artery disease. Glenn will need to reduce his dietary intake of total fat, saturated fats, and cholesterol, all of which contribute to raising LDL levels. Exercise will raise HDL levels. If those changes are not successful, drug therapy may be required.
3. The goal of weight loss programs is to reduce caloric intake so that the body utilizes stored lipids as an energy source. As part of that desired lipid metabolism, ketone bodies are produced. Some of these ketone bodies will be excreted in the urine. If no ketones are present, then Marissa's body is not breaking down lipids. Only through using fewer calories than needed will her body break down the stored fat and release ketones. Thus, she must be eating more calories than needed to support her daily activities—she is "cheating."

Chapter 26
1. Without reabsorption, initially 105–125mL of filtrate would be lost per minute, assuming normal glomerular filtration rate. Fluid loss from the blood would cause a decrease in blood pressure, and therefore a decrease in GBHP. When GBHP dropped below 45mmHg, filtration would stop (assuming normal CHF and BCOP) because NFP would be zero.
2. a. Although normally pale yellow, urine color can vary based upon concentration, diet, drugs, and disease. A dark yellow color would not necessarily indicate a problem, but further investigation may be needed. Turbidity or cloudiness can be caused by urine that has been standing for a period of time, from certain foods, or from bacterial infections. Further investigation is needed.
   b. Albumin should not be present in urine (or present in very small amounts) because it is too large to pass through the filtration membranes. The presence of high levels of albumin is cause for concern as it indicates damage to the filtration membranes.
3. Bruce has developed renal calculi (kidney stones), which are blocking his ureters and interfering with the flow of urine from the kidneys to the bladder. The rhythmic pains are a result of the peristaltic contractions of the ureters as they attempt to move the stones toward the bladder. Bruce can wait for the stones to pass, can have them surgically removed, or can use shock-wave lithotripsy to break apart the stones into smaller fragments that can be eliminated with urine. To prevent future episodes, Bruce needs to watch his diet (limit calcium), and drink fluids, and may need drug intervention.

Chapter 27
1. The loss of stomach acids can result in metabolic alkalosis. Robin's HCO₃⁻ levels would be higher than normal. She would be hyperventilating in order to decrease her pH by slowing the loss of CO₂. Excessive vomiting can result in hyponatremia, hypokalemia, and hypochloremia. Both hyponatremia and hypokalemia can cause mental confusion.
2. (Step 1) pH=7.30 indicates slight acidosis, which could be caused by elevated PCO₂ or lowered HCO₃⁻. (Step 2) The HCO₃⁻ is lower than normal (20mEq/liter), so (Step 3) the cause is metabolic. (Step 4) The PCO₂ is lower than normal (32mmHg), so hyperventilation is providing some compensation. Diagnosis: Henry has partially compensated metabolic acidosis. A possible cause is kidney damage that resulted from interruption of blood flow during the heart attack.
3. Sam will experience increased fluid loss through increased evaporation from the skin and water vapor from the respiratory system in order to maintain normal body temperature. His insensible water loss will also increase (loss of water from the respiratory system). Sam will have a decrease in urine formation.

Chapter 28
1. Monica's excessive training has resulted in an abnormally low amount of body fat. A certain amount of body fat is needed in order to produce the hormones required for the ovarian cycle. Several hormones are involved. Her amenorrhea is due to a lack of gonadotropin-releasing hormone, which in turn reduces the release of LH and FSH. Her follicles with their enclosed ova fail to develop and ovulation will not occur. In addition, synthesis of estrogens and
progesterone declines from the lack of hormonal feedback. Usually a gain of weight will allow normal hormonal feedback mechanisms to return.

2. Along with estrogens, progesterone helps to prepare the endometrium for possible implantation of a zygote by promoting growth of the endometrium. The endometrial glands secrete glycogen, which will help sustain an embryo if one should implant. If implantation occurs, progesterone helps maintain the endometrium for the developing fetus. In addition, it helps prepare mammary glands to secrete milk. It inhibits the release of GnRH and LH, which stops a new ovarian cycle from occurring.

3. The ductus deferens is cut and tied in a vasectomy. This stops the release of sperm into the ejaculatory duct and urethra. Mark will still produce the secretions from his accessory glands (prostate, seminal vesicles, bulbourethral glands) in his ejaculate. In addition, a vasectomy does not affect sexual performance; he will be able to achieve erection and ejaculation as those events are nervous system responses. Mark and Isabella will need to use additional protection for a period of time after the vasectomy as sperm can be stored in the ductus deferens and remain viable for several months. The physician will want to monitor his ejaculate for sperm levels for a short period of time.

Chapter 29

1. As part of the feedback mechanism for lactation, oxytocin is released from the posterior pituitary. It is carried to the mammary glands where it causes milk to be released into the mammary ducts (milk ejection). The oxytocin is also transported in the blood to the uterus, which contains oxytocin receptors on the myometrium. The oxytocin causes contraction of the myometrium, resulting in the painful sensations that Kathy is experiencing. The uterine contractions can help return the uterus back to its prepregnancy size.

2. Sex-linked genetic traits, such as hemophilia, are present on the X chromosomes but not on the Y chromosomes. In males, the X chromosome is always inherited from the mother, and the Y chromosome from the father. Thus, Jack’s hemophilia gene was inherited from his mother on his X chromosome. The gene for hemophilia is a recessive gene. His mother would need two recessive genes, one on each of her X chromosomes, to be hemophiliac. His father must carry the dominant (nonhemophiliac) gene on his X chromosome, so he also would not have hemophilia.

3. The cord blood is a source of pluripotent stem cells, which are unspecialized cells that have the potential to specialize into cells with specific functions. The hope is that stem cells can be used to generate cells and tissues to treat a variety of disorders. It is assumed that the tissues would not be rejected since they would contain the same genetic material as the patient—in this case Alisa’s baby.
### Pronunciation Key

1. The most strongly accented syllable appears in capital letters, for example, bilateral (bi-LAT-er-al) and diagnosis (di-ag-NÖ-sis).

2. If there is a secondary accent, it is noted by a prime (‘), for example, constitution (kon’sti-TOO-shun) and physiology (fiz’-o-OL-ö-jë). Any additional secondary accents are also noted by a prime, for example, decarboxylation (dé’-kar-bok’-si-LÄ-shun).

3. Vowels marked by a line above the letter are pronounced with the long sound, as in the following common words:
   - a as in mké         o as in pôle
   - e as in bè         à as in cîte
   - i as in ívy

4. Vowels not marked by a line above the letter are pronounced with the short sound, as in the following words:
   - a as in above or at  o as in not
   - e as in hêt        u as in bud
   - i as in sip

5. Other vowel sounds are indicated as follows:
   - oy as in oil
   - oo as in root

6. Consonant sounds are pronounced as in the following words:
   - b as in bat
   - ch as in chair
   - d as in dog
   - f as in father
   - g as in get
   - h as in hat
   - j as in jump
   - k as in can
   - ks as in tax
   - kw as in quit
   - l as in let

### GLOSSARY

- **Abdomen** (ab-DÔ-men or AB-dÔ-men) The area between the diaphragm and pelvis.

- **Abdominal** (ab-DOM-i-nal) cavity Superior portion of the abdominopelvic cavity that contains the stomach, spleen, liver, gallbladder, most of the small intestine, and part of the large intestine.

- **Abdominal thrust maneuver** A first-aid procedure for choking. Employs a quick, upward thrust against the diaphragm that forces air out of the lungs with sufficient force to eject any lodged material.

- **Abdominopelvic** (ab-dom’i-nô-PÉL-vik) cavity Inferior to the diaphragm that is subdivided into a superior abdominal cavity and an inferior pelvic cavity.

- **Abduction** (ab-DUK-shun) Movement away from the midline of the body.

- **Abortion** (a-BOR-shun) The premature loss (spontaneous) or removal (induced) of the embryo or nonviable fetus; miscarriage due to a failure in the normal process of developing or maturing.

- **Abscess** (AB-ses) A localized collection of pus and liquefied tissue in a cavity.

- **Absorption** (ab-SORP-shun) Intake of fluids or other substances by cells of the skin or mucous membranes; the passage of digested foods from the gastrointestinal tract into blood or lymph.

- **Accessory duct** A duct of the pancreas that empties into the duodenum about 2.5 cm (1 in.) superior to the ampulla of Vater (hepatopancreatic ampulla). Also called the duct of Santorini (san’-tôr-Í-né).

- **Acetabulum** (as’e-TAB-ú-lum) The rounded cavity on the external surface of the hip bone that receives the head of the femur.

- **Acetylcholine** (as’e-tël-KÔ-lën) (ACh) A neurotransmitter liberated by many peripheral nervous system neurons and some central nervous system neurons. It is excitatory at neuromuscular junctions but inhibitory at some other synapses (for example, it slows heart rate).

- **Achalasia** (ak’-al-LÄ-zé-a) A condition, caused by malfunction of the myenteric plexus, in which the lower esophageal sphincter fails to relax normally as food approaches. A whole meal may become lodged in the esophagus and enter the stomach very slowly. Distension of the esophagus results in chest pain that is often confused with pain originating from the heart.

- **Achilles tendon** See Calcaneal tendon.

- **Acini** (A-sé-i) Groups of cells in the pancreas that secrete digestive enzymes.

- **Acoustic** (a-KOOS-tik) Pertaining to sound or the sense of hearing.

- **Acquired immunodeficiency syndrome (AIDS)** A fatal disease caused by the human immunodeficiency virus (HIV). Characterized by a positive HIV-antibody test, low helper T cell count, and certain indicator diseases (for example Kaposi’s sarcoma, pneumocystis carinii pneumonia, tuberculosis, fungal diseases). Other symptoms include fever or night sweats, coughing, sore throat, fatigue, body aches, weight loss, and enlarged lymph nodes.

- **Acrosome** (ak-ro’söm) A lysosomalike organelle in the head of a sperm cell containing enzymes that facilitate the penetration of a sperm cell into a secondary oocyte.

- **Actin** (AK-tën) A contractile protein that is part of thin filaments in muscle fibers.

- **Action potential (AP)** An electrical signal that propagates along the membrane of a neuron or muscle fiber (cell); a rapid change in membrane potential that involves a depolarization followed by a repolarization. Also called a nerve action potential or nerve impulse as it relates to a neuron, and a muscle action potential as it relates to a muscle fiber.

- **Activation** (ak’ti-VÄ-shun) energy The minimum amount of energy required for a chemical reaction to occur.

- **Active transport** The movement of substances across cell membranes against a concentration gradient, requiring the expenditure of cellular energy (ATP).

- **Acute** (a-KÜT) Having rapid onset, severe symptoms, and a short course; not chronic.

- **Adaptation** (ad’ap-TÄ-shun) The adjustment of the pupil of the eye to changes in light intensity. The property by which a sensory neuron relays a decreased frequency of action potentials from a receptor, even though the strength of the stimulus remains constant; the decrease in perception of a sensation over time while the stimulus is still present.

- **Adduction** (ad-DUK-shun) Movement toward the midline of the body.

- **Adenoids** (AD-e-noyds) The pharyngeal tonsils.

- **Adenosine triphosphate** (a-DEN-e-trîf-ATP) (ATP) The main energy currency in living cells; used to transfer the chemical energy needed for metabolic reactions. ATP consists of the purine base adenine and the five-carbon sugar ribose, to which are added, in linear array, three phosphate groups.

- **Adhesion** (ad-HE-zhen) Abnormal joining of parts to each other.

- **Adipocyte** (AD-i-pö-sit) Fat cell, derived from a fibroblast.
**G2 GLOSSARY**

**Adipose** (AD-i-pöz) tissue  Tissue composed of adipocytes specialized for triglyceride storage and present in the form of soft pads between various organs for support, padding, and insulation.

**Adrenal cortex** (a-DR-e-nal KOR-teks) The outer portion of an adrenal gland, divided into three zones; the zona glomerulosa secretes mineralocorticoids, the zona fasciculata secretes glucocorticoids, and the zona reticularis secretes androgens.

**Adrenal glands** Two glands located superior to each kidney. Also called the **suprarenal** (soo-ar-E-nal) glands.

**Adrenal medulla** (me-DUL-a) The inner part of an adrenal gland, consisting of cells that secrete epinephrine, norepinephrine, and a small amount of dopamine in response to stimulation by sympathetic preganglionic neurons.

**Adrenergic** (ad-er-EN-rik) Pertaining to nerve fibers that release norepinephrine or epinephrine as their neurotransmitter.

**Adrenocorticotropic** (ad-REN-uh-kor-TIK-trop-ik) hormone (ACTH) A hormone produced by the anterior pituitary that influences the production and secretion of certain hormones of the adrenal cortex.

**Adventitia** (ad-ven-TISH-a) The outermost covering of a structure or organ.

**Aerobic** (air-oh-BIK) Requiring molecular oxygen.

**Afferent arteriole** (AF-er-ent ar-TEE-ro-l) A blood vessel of a kidney that divides into the capillary network called a glomerulus; there is one afferent arteriole for each glomerulus.

**Agglutination** (a-gloo-TUH-nay-shun) Clumping of microorganisms or blood cells, typically due to an antigen–antibody reaction.

**Aggregated lymphatic follicles** Clusters of lymph nodules that are most numerous in the ileum. Also called **Peyer’s (PI-erz) patches**.

**Albinism** (AL-bin-izm) Abnormal, nonpathological, partial, or total absence of pigment in skin, hair, and eyes.

**Aldosterone** (al-DOS-ter-ohn) A mineralocorticoid produced by the adrenal cortex that promotes sodium and water reabsorption by the kidneys and potassium excretion in urine.

**Allantois** (a-LAN-toh-iss) A small, vascularized outpouching of the yolk sac that serves as an early site for blood formation and development of the urinary bladder.

**Alleles** (a-LELZ) Alternate forms of a single gene that control the same inherited trait (such as type A blood) and are located at the same position on homologous chromosomes.

**Allergen** (AL-er-jen) An antigen that evokes a hypersensitivity reaction.

**Alopecia** (al-oh-PEE-uh-shun) The partial or complete lack of hair as a result of factors such as genetics, aging, endocrine disorders, chemotherapy, and skin diseases.

**Alpha** (AL-fa) A type of cell in the pancreatic islets (islets of Langerhans) in the pancreas that secretes the hormone glucagon. Also termed an A cell.

**Alpha receptor** A type of receptor for norepinephrine and epinephrine; present on visceral effectors innervated by sympathetic postganglionic neurons.

**Alveolar duct** Branch of a respiratory bronchiole around which alveoli and alveolar sacs are arranged.

**Alveolar macrophage** (MAK-roh-fay) Highly phagocytic cell found in the alveolar walls of the lungs. Also called a dust cell.

**Alveolar sac** A cluster of alveoli that share a common opening.

**Allele** An alternate form of a single gene that control the same inherited trait (such as type A blood) and are located at the same position on homologous chromosomes.

**Alopecia areata** A lack or loss of memory.

**Amenorrhea** (ah-men-oh-REE-a) Absence of menstruation.

**Ammnhesia** (am-NEE-uh-zhun) A lack or loss of memory.

**Amnion** (AM-nee-uhn) A thin, protective fetal membrane of the amniotic fluid. Also called the “bag of waters.”

**Amniotic fluid** (am-NEE-uh-tik) Fluid in the amniotic cavity, the space between the developing embryo (or fetus) and amnion; the fluid is initially produced as a filtrate from maternal blood and later includes fetal urine. It functions as a shock absorber, helps regulate fetal body temperature, and helps prevent desiccation.

**Amniocentesis** (am-NEE-oh-sen-tek-sis) A slightly movable joint, in which the articulating bony surfaces are separated by fibrous connective tissue or fibrocartilage to which both are attached; types are syndesmosis and symphysis.

**Ampulla** (am-PUL-la) A saclike dilation of a canal or duct.

**Ampulla of Vater** A saclike enlargement of a bile duct; part of the biliary tree (liver to duodenum).

**Aneurysm** (AN-yurz-im) A blood vessel caused by a weakening of its wall.

**Anal triangle** The posterior part of the perineum that contains the anus.

**Anal faucets** Membrane of the anal canal that contains a network of arteries and veins.

**Anal sac** A cluster of alveoli that share a common opening.

**Analgesia** (AN-a-JE-ze-uh) Pain relief; absence of pain.

**Anal triangle** The posterior part of the perineum that contains the anus.

**Anal canal** A slightly movable joint, in which the articulating bony surfaces are separated by fibrous connective tissue or fibrocartilage to which both are attached; types are syndesmosis and symphysis.

**Ampulla of Vater** A saclike enlargement of a bile duct; part of the biliary tree (liver to duodenum).

**Anaphylaxis** (AN-a-fal-uh-sis) The third stage of mitosis in which the centromeres move to opposite poles of the cell.

**Anaphase** (AN-a-fayz) The third stage of mitosis in which the centromeres move to opposite poles of the cell.

**Androgens** (AN-droh-jenz) Masculinizing sex hormones that promote growth and development of the male secondary sex characteristics (e.g., muscle mass, facial and body hair, and deepening of the voice in boys). The two main androgens are testosterone and dihydrotestosterone.

**Anemia** (AN-ee-mee-uh) Condition of the blood in which the number of functional red blood cells or their hemoglobin content is below normal.

**Anesthesia** (AN-ee-thee-uh) A total or partial loss of feeling or sensation; may be general or local.

**Aneurysm** (AN-ee-urz-um) A saclike enlargement of a blood vessel caused by a weakening of its wall.

**Angina pectoris** (ang-EEN-uh-puk-TOR-iss) A pain in the chest related to reduced coronary artery blood flow. It may be caused by atherosclerosis, spasm of the coronary arteries, or other factors.

**Angiogenesis** (ang-ee-JE-neh-sis) The formation of new blood vessels in the extraembryonic mesoderm of the yolk sac, connecting stalk, and chorion at the beginning of the third week of development.

**Ankylosis** (an-ki-LÖ-sis) Severe or complete loss of movement at a joint as the result of a disease process.

**Antagonist** (AN-ta-goh-nist) A muscle that has an action opposite that of the prime mover (agonist) and yields to the movement of the prime mover.

**Antagonistic** (an-ta-goh-NEE-ystick) Effect A hormonal interaction in which the effect of one hormone on a target cell is opposed by another hormone. For example, calcitonin (CT) lowers blood calcium level, whereas parathyroid hormone (PTH) raises it.

**Anterior pituitary** Anterior lobe of the pituitary gland. Also called the **adenohypophysis** (ad-ee-noh-HIP-oh-fy-sis).

**Anterior root** The structure composed of axons of motor (efferent) neurons that emerges from the anterior aspect of the spinal cord and extends laterally to join a posterior root, forming a spinal nerve. Also called a ventral root.

**Anterolateral pathway** Sensory pathway that conveys information related to pain, temperature, tickle, and itch.
Antibody (AN-ti-bod'-e) A protein produced by plasma cells in response to a specific antigen; the antibody combines with that antigen to neutralize, inhibit, or destroy it. Also called an immunoglobulin (im-nö-OG-LOB-ih-lin) or Ig.

Anticoagulant (an-ti-co'AG-lant) A substance that can delay, suppress, or prevent the clotting of blood.

Antidiuretic (an-ti-dyoo-RET-ik) Substance that inhibits urine formation.

Antidiuretic hormone (ADH) Hormone produced by neurosecretory cells in the paraventricular and supraoptic nuclei of the hypothalamus that stimulates water reabsorption from kidney tubule cells into the blood and vasoconstriction of arterioles. Also called vasopressin (vaz-OPRES-in).

Antigen (AN-ti-jen) A substance that has immunogenicity (the ability to provoke an immune response) and reactivity (the ability to react with the antibodies or cells that result from the immune response); contraction of antibody generator. Also termed a complete antigen.

Antigen-presenting cell (APC) Special class of migratory cell that processes and presents antigens to T cells during an immune response; APCs include macrophages, B cells, and dendritic cells, which are present in the skin, mucous membranes, and lymph nodes.

Antrum (AN-trum) Any nearly closed cavity or chamber, especially one within a bone, such as a sinus.

Anuria (AN-ü-ree-a) Absence of urine formation or daily urine output of less than 50 mL.

Anus (AN-us) The distal end and outlet of the rectum.

Aorta (OR-ta) The main systemic trunk of the arterial system of the body that emerges from the left ventricle.

Aortic (OR-tik) body Cluster of chemoreceptors on or near the arch of the aorta that respond to changes in blood levels of oxygen, carbon dioxide, and hydrogen ions (H+).

Aortic reflex A reflex that helps maintain normal systemic blood pressure; initiated by baroreceptors in the wall of the ascending aorta and arch of the aorta. Nerve impulses from aortic baroreceptors reach the cardiovascular center via sensory axons of the vagus (X) nerves.

Apex (AP-seks) The pointed end of a conical structure, such as the apex of the heart.

Aphasia (a-FA-zhe-a) Loss of ability to express oneself properly through speech or loss of verbal comprehension.

Apnea (AP-ne-a) Temporary cessation of breathing.

Apneustic (ap-NOO-stik) area A part of the respiratory center in the pons that sends stimulatory nerve impulses to the inspiratory area that activates and prolongs inhalation and inhibits exhalation.

Apocrine (AP-ör-kin) gland A type of gland in which the secretory products gather at the free end of the secreting cell and are pinched off, along with some of the cytoplasm, to become the secretion, as in mammary glands.

Aphineurosis (ap'-ör-noo-RO-sis) A sheetlike tendon joining one muscle with another or with bone.

Apoptosis (ap'-Ö-to-sis or ap'-ö-To-sis) Programmed cell death; a normal type of cell death that removes unneeded cells during embryological development, regulates the number of cells in tissues, and eliminates many potentially dangerous cells such as cancer cells. During apoptosis, the DNA fragments, the nucleus condenses, mitochondria cease to function, and the cytoplasm shrinks, but the plasma membrane remains intact. Phagocytes engulf and digest the apoptotic cells, and an inflammatory response does not occur.

Appositional (ap'-Ö-ZISH-onal) growth Growth due to surface deposition of material, as in the growth in diameter of cartilage and bone. Also called exogenous (eks-OJ-en-sis) growth.

Aqueous humor (AK-wë-us HÜ-mer) The watery fluid, similar in composition to cerebrospinal fluid, that fills the anterior cavity of the eye.

Araclon (RAK-noid) mater The middle of the three meninges (coverings) of the brain and spinal cord. Also termed the arachnoid.

Araclon villus (VIL-us) Berrylike tuft of the arachnoid mater that protrudes into the superior sagittal sinus and through which cerebrospinal fluid is reabsorbed into the bloodstream.

Arbor vitae (AR-bor VI-të) The white matter tracts of the cerebellum, which have a treelike appearance when seen in midsagittal section.

Arch of the aorta The most superior portion of the aorta, lying between the ascending and descending segments of the aorta.

Area (a-RE-ö-la) Any tiny space in a tissue. The pigmented ring around the nipple of the breast.

Arm The part of the upper limb from the shoulder to the elbow.

Arousal (a-ROW-zal) Awakening from sleep, a response due to stimulation of the reticular activating system (RAS).

Arrector pili A-ROW-zal) A smooth muscle attached to hairs; contraction pulls the hairs into a vertical position, resulting in “goose bumps.”

Arrhythmia (a-RITH-më-a) An irregular heartbeat rhythm. Also called a dysrhythmia.

Arteriole (ar-TE–-re-o-lee) A small, almost microscopic, artery that delivers blood to a capillary.

Artherosclerosis (ar-ter-Ö-skle-RÖ-sis) Group of diseases characterized by thickening of the walls of arteries and loss of elasticity.

Artery (AR-ter-e) A blood vessel that carries blood away from the heart.

Asthma (AZ-ma) Usually allergic reaction characterized by smooth muscle spasms in bronchi resulting in wheezing and difficult breathing. Also called bronchial asthma.

Astigmatism (a-STIG-ma-tizm) An irregularity of the lens or cornea of the eye causing the image to be out of focus and producing faulty vision.

Astrocyte (AS-tro-sye-t) A neuroglial cell having a process that branches, and contains a capacity to store potassium, which can be released to level out potassium concentrations of neurons.

Atrophy (a-TROF-ë-a) A decrease in size or bulk of a muscle or organ. Also called a wasting.

Atria (A-tré-a) A chamber, especially one within a bone, such as a sinus.

Atresia (a-TRE–-ze-a) Congenital absence or closure of an orifice. Also called a congenital absence.

Atrophic (a-TROF-ik) plaque (PLAK) A lesion that results from accumulated cholesterol and smooth muscle fibers (cells) of the tunica media of an artery; may become obliterative.

Atom Unit of matter that makes up a chemical element; consists of a nucleus (containing positively charged protons and uncharged neutrons) and negatively charged electrons that orbit the nucleus.

Atrophy (a-TROF-ë-a) Degeneration and reabsorption of an ovarian follicle before it fully matures and ruptures; abnormal closure of a passage, or absence of a normal body opening.

Atrial fibrillation (A-tré-al fibr-ri-LÄ-shun) Asynchronous contraction of cardiac muscle fibers in the atria that results in the cessation of atrial pumping.
**Atrial natriuretic (na-tř-ě-RET-ik) peptide (ANP)**
Peptide hormone, produced by the atria of the heart in response to stretching, that inhibits aldosterone production and thus lowers blood pressure; causes natriuresis, increased urinary excretion of sodium.

**Atrioventricular (AV)** (á-tré-o-ven-TRIK-tlar) bundle The part of the conduction system of the heart that begins at the atrioventricular (AV) node, passes through the cardiac skeleton separating the atria and the ventricles, then extends a short distance down the interventricular septum before splitting into right and left bundle branches. Also called the bundle of His (HIS).

**Atrioventricular (AV) node** The part of the conduction system of the heart made up of a compact mass of conducting cells located in the septum between the two atria.

**Atrioventricular (AV) valve** A heart valve made up of membranous flaps or cusps that allows blood to flow in one direction only, from an atrium into a ventricle.

**Atrium** (Ath-ri-um) A superior chamber of the heart.

**Atrophy** (Ath-ro-fe) Wasting away or decrease in size of a part, due to a failure, abnormality of nutrition, or lack of use.

**Auditory ossicle** (AW-di-to¯-re¯ OS-si-kul) One of the three small bones of the middle ear called the malleus, incus, and stapes.

**Auditory tube** The tube that connects the middle ear with the nose and nasopharynx region of the throat. Also called the eustachian (ē-STĀ-shun) or e-STĀ-kē-an) tube or pharyngotympanic tube.

**Auscultation** (AW-skul-TĀ-shun) Examination by listening to sounds in the body.

**Autoimmunity** An immunological response against a person’s own tissues.

**Autoysis** (aw-TOL-i-sis) Self-destruction of cells by their own lysosomal digestive enzymes after death or in a pathological process.

**Autonomic ganglion** (aw-TOL-i-sis) A cluster of cell bodies of sympathetic or parasympathetic neurons located outside the central nervous system.

**Autonomic nervous system (ANS)** Visceral sensory (afferent) and visceral motor (efferent) neurons. Autonomic motor neurons, both sympathetic and parasympathetic, convey nerve impulses from the central nervous system to smooth muscle, cardiac muscle, and glands. So named because this part of the nervous system was thought to be self-governing or spontaneous.

**Autonomic plexus** (PLEK-sus) A network of sympathetic and parasympathetic axons; examples are the cardiac, celiac, and pelvic plexuses, which are located in the thorax, abdomen, and pelvis, respectively.

**Autophagy** (aw-TOF-ą-jē) Process by which worn-out organelles are digested within lysosomes.

**Autopsy** (AW-top-sē) The examination of the body after death.

**Auricularis cells** Cardiac or smooth muscle fibers that are self-excitable (generate impulses without an external stimulus); act as the heart’s pacemaker and conduct the pacing impulse through the conduction system of the heart; self-excitable neurons in the central nervous system, as in the inspiratory area of the brain stem.

**Autosome** (AW-tō-sōm) Any chromosome other than the X and Y chromosomes (sex chromosomes).

**Axilla** (ak-SIL-ą) The small hollow beneath the arm where it joins the body at the shoulders. Also called the armpit.

**Axon** (AK-sōn) The usually single, long process of a nerve cell that propagates a nerve impulse toward the axon terminals.

**Axon terminal** Terminal branch of an axon where synaptic vesicles undergo exocytosis to release neurotransmitter molecules.

**B**

**B cell** A lymphocyte that can develop into a clone of antibody-producing plasma cells or memory cells when properly stimulated by a specific antigen.

**Babinski** (ba-BIN-sē) sign Extension of the great toe, with or without fanning of the other toes, in response to stimulation of the outer margin of the sole; normal up to 18 months of age and indicative of damage to descending motor pathways such as the corticospinal tracts after that.

**Back** The posterior part of the body; the dorsum.

**Ball-and-socket joint** A synovial joint in which the rounded surface of one bone moves within a cup-shaped depression or socket of another bone, as in the shoulder or hip joint. Also called a spheroid (SFR-roid) joint.

**Baroreceptor** (bar-ő-re-SEP-tor) Neuron capable of responding to changes in blood, air, or fluid pressure. Also called a pressure receptor.

**Basal ganglia** (BÁ-so-fil) A type of white blood cell

**Basilar** (BA-SI-lar) A type of adrenergic receptor for epinephrine and norepinephrine; found on visceral effector innervated by sympathetic postganglionic neurons.

**Bicuspid** (ki-KUS-pid) Pertaining to two sides of the body.

**Bile** (BIL) A secretion of the liver consisting of water, bile salts, bile pigments, cholesterol, lecithin, and several ions; it emulsifies lipids prior to their digestion.

**Bilirubin** (bil-ě-RO-bin) An orange pigment that is one of the end products of hemoglobin breakdown in the hepatocytes and is excreted as a waste material in bile.

**Blastocyst** (BLAS-tō-sēst) In the development of an embryo, a hollow ball of cells that consists of a blastocyst (the internal cavity), trophoblast (outer cells), and embryoblast (inner cell mass).

**Blastocyst** (BLAS-tō-sēst) cavity The fluid-filled cavity within the blastocyst. Also called the blastocoele.

**Blastomere** (BLAS-tō-mēr) One of the cells resulting from the cleavage of a fertilized ovum.

**Blood island** Isolated mass of mesoderm derived from angioblasts and from which blood vessels develop.

**Blood pressure (BP)** Force exerted by blood against the walls of blood vessels due to contraction of the heart and influenced by the elasticity of the vessel walls; clinically, a measure of the pressure in arteries during ventricular systole and ventricular diastole.

**Blood reservoir** (REZ-er-vwar) Systemic veins and venules that contain large amounts of blood that can be moved quickly to parts of the body requiring the blood.

**Blood–brain barrier (BBB)** A barrier consisting of specialized brain capillaries and astrocytes that prevents the passage of materials from the blood to the cerebrospinal fluid and brain.

**Blind spot** Area in the retina at the end of the optic (II) nerve in which there are no photoreceptors.

**Blood** The fluid that circulates through the heart, arteries, capillaries, and veins and that constitutes the chief means of transport within the body.

**Blood–brain barrier (BBB)** A barrier consisting of specialized brain capillaries and astrocytes that prevents the passage of materials from the blood to the cerebrospinal fluid and brain.

**Blood island** Isolated mass of mesoderm derived from angioblasts and from which blood vessels develop.

**Blood pressure (BP)** Force exerted by blood against the walls of blood vessels due to contraction of the heart and influenced by the elasticity of the vessel walls; clinically, a measure of the pressure in arteries during ventricular systole and ventricular diastole.

**Blood reservoir** (REZ-er-vwar) Systemic veins and venules that contain large amounts of blood that can be moved quickly to parts of the body requiring the blood.

**Blood–testis barrier (BTB)** A barrier formed by Sertoli cells that prevents an immune response against antigens produced by spermatogenic cells by isolating the cells from the blood.

**Body cavity** A space within the body that contains various internal organs.

**Bolus** (Bō-lus) A soft, rounded mass, usually food, that is swallowed.

**Bony labyrinth** (LAB-i-rinth) A series of cavities within the petrous portion of the temporal bone forming the vestibule, cochlea, and semicircular canals of the inner ear.

**Bowman’s capsule** See Glomerular capsule.

**Brachial plexus** (BRÁ-kē-al PLEK-sus) A network of nerve axons of the ventral rami of spinal nerves C5, C6, C7, C8, and T1. The nerves that emerge from the brachial plexus supply the upper limb.

**Bradycardia** (bräd-ī-KAR-de-ă) A slow resting heart or pulse rate (under 50 beats per minute).

**Brain** The part of the central nervous system contained within the cranial cavity.

**Brain stem** The portion of the brain immediately superior to the spinal cord, made up of the medulla oblongata, pons, and midbrain.
Brain waves  Electrical signals that can be recorded from the skin of the head due to electrical activity of brain neurons.

Broad ligament  A double fold of parietal peritoneum attaching the uterus to the side of the pelvic cavity.  Also called the motor speech area.

Broca’s (BRÖ-kaz) area  Motor area of the brain in the frontobasal lobe that translates thoughts into speech. Also called the speech area.

Bronchi (BRON-ki) Branches of the respiratory pas sageway including primary bronchi (the two divisions of the trachea), secondary or lobar bronchi (divisions of the primary bronchi that are distributed to the lobes of the lung), and tertiary or segmental bronchi (divisions of the secondary bronchi that are distributed to bronchopulmonary segments of the lung). Singular is bronchus.

Bronchial tree  The trachea, bronchi, and their branching structures up to and including the terminal bronchioles.

Bronchiole (BRONG-ké-ol) Branch of a tertiary bronchiole further dividing into terminal bronchioles (distributed to lobules of the lung), which divide into respiratory bronchioles (distributed to alveolar sacs).

Bronchitis (brong-KI-tis) Inflammation of the mucous membrane of the bronchial tree; characterized by hypertrophy and hyperplasia of seromucous glands and goblet cells that line the bronchi which results in a productive cough.

Bronchopulmonary (brong’-kō-PUL-mō-ner-ē) segment  One of the smaller divisions of a lobe of a lung supplied by its own branches of a bronchus.

Brunner’s gland See Duodenal gland.

Buccal (boo-LIM-e-ā) A disorder characterized by overeating at least twice a week followed by purging by self-induced vomiting, strict dieting or fasting, vigorous exercise, or use of laxatives or diuretics. Also called binge-purge syndrome.

Bulk-phase endocytosis  A process by which most body cells can ingest membrane-surrounded droplets of interstitial fluid.

Bundle branch  One of the two branches of the atrioventricular (AV) bundle made up of specialized muscle fibers (cells) that transmit electrical impulses to the ventricles.

Bundle of His See Atrioventricular (AV) bundle.

Bursa (BUR-sa) A sac or pouch of synovial fluid that lubricates joints, especially about joints.

Bursitis (bur-SI-tis) Inflammation of a bursa.

Buttocks (BUT-oks) The two fleshy masses on the posterior aspect of the inferior trunk, formed by the gluteal muscles.

Calcaneal (kal-KĀ-nē-āl) tendon  The tendon of the soleus, gastrocnemius, and plantaris muscles at the back of the heel. Also called the Achilles (ak-ILL-ēs) tendon.

Calcification (kal’s-fi-KĀ-shun) Deposition of mineral salts, primarily hydroxyapatite, in a framework formed by collagen fibers in which the tissue hardens. Also called mineralization (min’-ē-ral-i-ZĀ-shun).

Calcitonin (kal-si-TÖ-nin) (CT) A hormone produced by the parafollicular cells of the thyroid gland that can lower the amount of blood calcium and phosphates by inhibiting bone resorption (breakdown of bone extracellular matrix) and by accelerating uptake of calcium and phosphates into bone matrix.

Calcus (KAL-kō-lus) A stone, or insoluble mass of crystallized salts or other material, formed within the body, as in the gallbladder, kidney, or urinary bladder.

Callus (KAL-lus) A growth of new bone tissue in and around a fractured area, ultimately replaced by bone. An acquired, localized thickening.

Callyx (KAL-iks) Any cuplike division of the kidney pelvis. Plural is callyses (KAL-ī-sēz).

Canal (kal-NAL) A narrow tube, channel, or pas sageway.

Canaliculus (kan’-a-LIK-ū-lus) A small channel or canal, as in bones, where they connect lacunae. Plural is canaliculi (kan’-a-LIK-ū-lī).

Canal of Schlemm See Scleral venous sinus.

Carcinogen  An agent that can initiate or promote the development of a neoplastic (cancerous) lesion.

Carcinogenesis  The process by which a cell becomes cancerous (carcinoma).

Cardiac muscle  Striated muscle fibers (cells) that form the wall of the heart; stimulated by an intrinsic conduction system and autonomic motor neurons.

Cardiac cycle  A complete heartbeat consisting of systole (contraction) and diastole (relaxation) of both atria plus systole and diastole of both ventricles.

Cardiogenic area  A group of cells in the heart that form the wall of the heart; stimulated by an intrinsic conduction system and autonomic motor neurons.

Cardiomegaly  See Enlarged heart.

Cardiovascular (kar-dē-ō-VAS-kō-lar) center  Groups of neurons scattered within the medulla oblongata that regulate heart rate, force of contraction, and blood vessel diameter.

Carotene (Kar-ō-tēn) Antioxidant precursor of vitamin A, which is needed for synthesis of yellow-orange pigment present in the stratum corneum of the epidermis. Accounts for the yellow-orange coloration of skin. Also termed beta-carotene.

Carotid (kar-ōt-id) body  Cluster of chemoreceptors on or near the carotid sinus that respond to changes in blood levels of oxygen, carbon dioxide, and hydrogen ions.

Carotid sinus  A dilated region of the internal carotid artery just superior to where it branches from the common carotid artery; it contains baroreceptors that monitor blood pressure.

Carpal bones  The eight bones of the wrist. Also called carpal bones.

Carpus (kar-pus) A collective term for the eight bones of the wrist.

Cartilage (kar-ti-JEN-ik) A group of connective tissue consisting of chondrocytes in lacunae embedded in a dense network of collagen and elastic fibers and an extracellular matrix of chondroitin sulfate.

Cartilaginous (kar-ti-LAJ-i-nus) joint  A joint without a synovial (joint) cavity where the articulating bones are held tightly together by cartilage, allowing little or no movement.

Catabolism (ka-TAB-ō-lizm) Chemical reactions that break down complex organic compounds into simple ones, with the net release of energy.

Cataract (kat-ar-akt) Loss of transparency of the lens of the eye or its capsule or both.

Cauda equina (KAW-da e-kwē-ä) A tail-like array of roots of spinal nerves at the inferior end of the spinal cord.

Caudal (KAU-dal) Pertaining to any tail-like structure; inferior in position.

Cecum (SE-kūm) A blind pouch at the proximal end of the large intestine that attaches to the ileum.

Celiac plexus (PLEK-sus) A large mass of autonomic ganglia and axons located at the level of the superior part of the first lumbar vertebra. Also called the solar plexus.

Cell  The basic structural and functional unit of all organisms; the smallest structure capable of performing all the activities vital to life.

Cell cycle  Growth and division of a single cell into two identical cells; consists of interphase and cell division.

Cell division  Process by which a cell reproduces itself that consists of a nuclear division (mitosis) and a cytoplasmic division (cytokinesis); types include somatic and reproductive cell division.

Cell junction  Point of contact between plasma membranes of tissue cells.

Cementum (se-MEN-tum) Calcified tissue covering the root of a tooth.

Central canal  A microscopic tube running the length of the spinal cord in the gray commissure. A circumferential channel running longitudinally in the center of an osteon (haversian system) of mature compact bone, containing blood and lymphatic vessels and nerves. Also called an haversian (ha-VERS-shun) canal.

Central fovea (FO-vē-ä) A depression in the center of the macula lutea of the retina, containing...
Cones only and lacking blood vessels; the area of highest visual acuity (sharpness of vision).

Central nervous system (CNS) That portion of the nervous system that consists of the brain and spinal cord.

Centrioles (SEN-tré-0lz) Paired, cylindrical structures of a centrosome, each consisting of a ring of microtubules and arranged at right angles to each other.

Centromere (SEN-tró-mér) The constricted portion of a chromosome where the two chromatids are joined; serves as the point of attachment for the microtubules that pull chromatids during anaphase of cell division.

Centrosome (SEN-tro-0m) A dense network of microtubules near the nucleus of a cell, containing a pair of centrioles and pericentriolar material.

Cephalic (se-FAL-ik) Pertaining to the head; superior in position.

Cerebellar peduncle (ser-e-BEL-ar pe-DUNG-kul) A bundle of nerve axons connecting the cerebellum with the brain stem.

Cerebellum (ser-e-BEL-um) The part of the brain lying posterior to the medulla oblongata and pons; governs balance and coordinates skilled movements.

Cerebral aqueduct (SER-e¯-bral AK-we-dukt) A channel through the midbrain connecting the third and fourth ventricles and containing cerebrospinal fluid. Also termed the aqueduct of Sylvius.

Cerebral arterial circle A ring of arteries forming an anastomosis at the base of the brain between the internal carotid and basilar arteries and arteries supplying the cerebral cortex. Also called the circle of Willis.

Cerebral cortex The surface of the cerebral hemispheres, 2–4 mm thick, consisting of gray matter; arranged in six layers of neuronal cell bodies in most areas.

Cerebral peduncle One of a pair of nerve axon bundles located on the anterior surface of the midbrain, conducting nerve impulses between the pons and the cerebral hemispheres.

Cerebrospinal fluid (se-re-0-BRA-spinal) fluid (CSF) A fluid produced by ependymal cells that cover choroid plexuses in the ventricles of the brain; the fluid circulates in the ventricles, the central canal, and the subarachnoid space around the brain and spinal cord.

Cerebrovascular (se-re-0-VAS-ka-lar) accident (CVA) Destruction of brain tissue (infarction) resulting from obstruction or rupture of blood vessels that supply the brain. Also called a stroke or brain attack.

Cerebrum (SER-e-brum or se-RÉ-brum) The two hemispheres of the forebrain (derived from the telencephalon), making up the largest part of the brain.

Cerumen (se-ROO-men) Waxlike secretion produced by ceruminous glands in the external auditory meatus (ear canal). Also termed ear wax.

Ceruminous (se-ROO-mí-nus) gland A modified sudoriferous (sweat) gland in the external auditory meatus that secretes cerumen (ear wax).

Cervical ganglion (SER-vi-kul GANG-glé-on) A cluster of cell bodies of postganglionic sympathetic neurons located in the neck, near the vertebral column.

Cerebellum (SER-e¯-brum) The part of the brain lying posterior to the medulla oblongata and pons; governs balance and coordinates skilled movements.

Chiasm (KÍ-azm) A crossing; especially the crossing of axons in the optic (II) nerve.

Chief cell The secreting cell of a gastric gland that produces pepsinogen, the precursor of the enzyme pepsin, and the enzyme gastric lipase. Also called a zymogenic (zi-mó-jén-ik) cell. Cell in the parathyroid glands that secretes parathyroid hormone (PTH). Also called a principal cell.

Choleduct (kó-LED-ikt) A bundle of nerve axons connecting the cerebellar hemispheres, giving rise to the spinal cord and the subarachnoid space around the brain and spinal cord.

Cholelithiasis (kó-LEL-i-the-sis) Surgical removal of the gallbladder.

Cholecystectomy (kó-LE-sis-tek-to-my) Surgical removal of the gallbladder.

Cholesterin (kon-DROY-tin) Chondrocyte

Cholinergic (ko¯-lin-ER-jik) A neuron that produces acetylcholine as its neurotransmitter.

Chondrocyte (KÓN-dró-sit) Cell of mature cartilage.

Chondroitin (kon-DROY-tin) Chondroitin sulfate An amorphous extracellular matrix material found outside connective tissue cells.

Chordae tendineae (KOR-dé TEN-dí-né-é) Tendinous fibers that connect atrioventricular valves of the heart with papillary muscles.

Chorion (KRO¯-mion) The outermost of the three layers of the placenta; serves a protective and nutritive function.

Chorionic villi (kó-ri-ON-ik VIL-lí) Fingerlike projections of the chorion that grow into the decidua basalis of the endometrium and contain fetal blood vessels.

Chorionic villi sampling (CVS) The removal of a sample of chorionic villus tissue by means of a catheter to analyze the tissue for prenatal genetic defects.

Choroid (KÓ-royd) One of the vascular coats of the eyeball.

Choroid Plexus (PLEK-sus) A network of capillaries located in the roof of each of the four ventricles of the brain; ependymal cells around choroid plexuses produce cerebrospinal fluid.

Chromafin (KRÓ-maf-in) cell Cell that has an affinity for chrome salts, due in part to the presence of the precursors of the neurotransmitter epinephrine; found, among other places, in the adrenal medulla.

Chromatin (KRÓ-má-tén) A network formed by the precursors of the neurotransmitter epinephrine and pericentriolar material that becomes the principal embryonic portion of the placenta; serves a protective and nutritive function.

Chromatid (KRÓ-má-tid) One of a pair of identical connected nuclear protein strands that are joined at the centromere and separate during cell division, each becoming a chromosome of one of the two daughter cells.

Chromatin (KRÓ-ma-tén) The threadlike mass of genetic material, consisting of DNA and histone proteins, that is present in the nucleus of a nondividing or interphase cell.

Chromatolysis (kro¯-ma-tol-i-sis) The breakdown of Nissl bodies into finely granular masses in the cell body of a neuron whose axon has been damaged.

Chromosome (KRÓ-mó-sóm) One of the small, threadlike structures in the nucleus of a cell, normally 46 in a human diploid cell, that bears the genetic material; composed of DNA and proteins (histones) that form a delicate chromatin thread during interphase; becomes packaged into compact rodlike structures that are visible under the light microscope during cell division.

Chronic (KRON-ik) Long term or frequently recurring; applied to a disease that is not acute.

Chronic obstructive pulmonary disease (COPD) A disease, such as bronchitis or emphysema, in which there is some degree of obstruction of airways and consequent increase in airway resistance.

Chyle (KÍL) The milky-appearing fluid found in the lacteals of the small intestine after absorption of lipids in food.

Chyme (KÍM) The semifluid mixture of partly digested food and digestive secretions found in the stomach and small intestine during digestion of a meal.

Ciliary (SIL-é-ar-) body One of the three parts of the vascular tunic of the eyeball, the others being the choroid and the iris; includes the ciliary muscle and the ciliary processes.

Ciliary ganglion (GANG-glé-on) A very small parasympathetic ganglion whose preganglionic axons come from the oculomotor (III) nerve and whose postganglionic axons carry nerve impulses to the ciliary muscle and the sphincter muscle of the iris.

Cilium (SIL-é-um) A hair or hair-like process projecting from a cell that may be used to move the entire cell or to move substances along the surface of the cell. Plural is cilia.

Circle of Willis See Cerebral arterial circle.

Circular folds Permanent, deep, transverse folds in the mucosa and submucosa of the small intestine that increase the surface area for absorption. Also called plicae circulares (PLÍ-ké SER-kó-lar-es).

Circumduction (ser-kum-DUK-shun) A movement at a synovial joint in which the distal end of a bone moves in a circle while the proximal end remains relatively stable.

Cirrhosis (si-RO-sís) A liver disorder in which the parenchymal cells are destroyed and replaced by connective tissue.

Cisterna chyli (si-s-TÉ-rah KÍ-lé) The origin of the thoracic duct.

Cleavage The rapid mitotic divisions following the fertilization of a secondary oocyte, resulting in
an increased number of progressively smaller cells, called blastomeres.

Clitoris (KLI-to-ris) An erectile organ of the female, located at the anterior junction of the labia minora, that is homologous to the male penis.

Clone (KLO-N) A population of identical cells.

Coartation (kō-ark-TÄ-shun) of the aorta A congenital heart defect in which a segment of the aorta is too narrow. As a result, the flow of oxygenated blood to the body is reduced, the left ventricle is forced to pump harder, and high blood pressure develops.

Coccyx (KOK-siks) The fused bones at the inferior end of the vertebral column.

Cochlea (KOK-le-a) A winding, cone-shaped tube that develops at the end of the vertebral column.

Collateral circulation The alternate route taken by blood through an anastomosis.

Coliculus (ko-LIK-ù-lus) A small elevation.

Colon The portion of the large intestine consisting of ascending, transverse, descending, and sigmoid portions.

Column (ko-LUM) A group of white matter tracts in the spinal cord.

Common bile duct A tube formed by the union of the common hepatic duct and the cystic duct that contains several ductules so that both are directed toward a near object being viewed in order to produce a single image.

Cornea (KOR-ne-a) The nonvascular, transparent covering of the eye.

Cortex The external layer of the brain; pass through foramina in the skull; and supply sensory and motor neurons to the head, neck, part of the trunk, and viscera of the thorax and abdomen.

Cryptorchidism (krip-TOR-ki-dizm) The condition in which the testes fail to descend into the scrotum.

Cranial nerve One of 12 pairs of nerves that leave the cranial bones and containing the cranial cavity.

Cranium (kra-NI-um) The skull, part of the trunk, and viscera of the thorax and abdomen.

Cupula (KU-pu-la) A mass of gelatinous material in the ampulla of a semicircular canal.

Cortex (KOR-teks) An outer layer of an organ. The convoluted layer of gray matter covering each cerebral hemisphere.

Costal (KOSS) Pertaining to a rib.

Cryptorchidism (krip-TOR-ki-dizm) The condition in which the testes fail to descend into the scrotum.

Cranial nerve One of 12 pairs of nerves that leave the cranial bones and containing the cranial cavity.

Cranial (KRA-ne-al) A cavity within the cranial cavity.

Cranial nerve One of 12 pairs of nerves that leave the cranial bones and containing the cranial cavity.

Cramp A spasmodic, usually painful contraction of a muscle.

Craniosacral (kra-NI-o-SA-Kral) The movement of the cranial bones and containing the cranial cavity.

Crossing-over An exchange of genes among chromatids and is one factor that results in genetic variation of progeny.

Crista (KRIS-ta) A crest or ridged structure. A section of the diaphragm which is directed toward a near object being viewed in order to produce a single image.

Cupula (KU-pu-la) A mass of gelatinous material in the ampulla of a semicircular canal.

Corpus albicans (KOR-pus AL-bi-kanz) A white fibrous patch in the ovary that forms after the corpus luteum regresses.

Corpus luteum (LOO-te-um) A yellowish body in the ovary formed when a follicle has discharged its secondary oocyte; secretes estrogens, progesterone, relaxin, and inhibin.

Corpus striatum (str-A-tum) An area in the interior of each cerebral hemisphere composed of the caudate and putamen of the basal ganglia and white matter of the internal capsule, arranged in a striated manner.

Corpuscle of touch A sensory receptor in the ampulla of each semicircular canal that contains receptors for dynamic equilibrium.

Crista (KRIS-ta) A crest or ridged structure. A section of the diaphragm which is directed toward a near object being viewed in order to produce a single image.

Crossing-over An exchange of genes among chromatids and is one factor that results in genetic variation of progeny.

Crus (KRUSS) A scroll-like bone found in the skull.

Cuff (KUF) Pertaining to a rib.

Cupula (KU-pu-la) A mass of gelatinous material in the ampulla of a semicircular canal.

Corpus albicans (KOR-pus AL-bi-kanz) A white fibrous patch in the ovary that forms after the corpus luteum regresses.

Corpus striatum (str-A-tum) An area in the interior of each cerebral hemisphere composed of the caudate and putamen of the basal ganglia and white matter of the internal capsule, arranged in a striated manner.

Cortex (KOR-teks) An outer layer of an organ. The convoluted layer of gray matter covering each cerebral hemisphere.

Costal (KOSS) Pertaining to a rib.

Cryptorchidism (krip-TOR-ki-dizm) The condition in which the testes fail to descend into the scrotum.

Cranial nerve One of 12 pairs of nerves that leave the cranial bones and containing the cranial cavity.

Cranial (KRA-ne-al) A cavity within the cranial cavity.

Cranial nerve One of 12 pairs of nerves that leave the cranial bones and containing the cranial cavity.

Cramp A spasmodic, usually painful contraction of a muscle.

Cranial (KRA-ne-al) A cavity within the cranial cavity.

Cranial nerve One of 12 pairs of nerves that leave the cranial bones and containing the cranial cavity.

Crista (KRIS-ta) A crest or ridged structure. A section of the diaphragm which is directed toward a near object being viewed in order to produce a single image.

Crossing-over An exchange of genes among chromatids and is one factor that results in genetic variation of progeny.

Crus (KRUSS) A scroll-like bone found in the skull.

Cuff (KUF) Pertaining to a rib.

Cupula (KU-pu-la) A mass of gelatinous material in the ampulla of a semicircular canal.

Corpus albicans (KOR-pus AL-bi-kanz) A white fibrous patch in the ovary that forms after the corpus luteum regresses.

Corpus luteum (LOO-te-um) A yellowish body in the ovary formed when a follicle has discharged its secondary oocyte; secretes estrogens, progesterone, relaxin, and inhibin.

Corpus striatum (str-A-tum) An area in the interior of each cerebral hemisphere composed of the caudate and putamen of the basal ganglia and white matter of the internal capsule, arranged in a striated manner.

Cortex (KOR-teks) An outer layer of an organ. The convoluted layer of gray matter covering each cerebral hemisphere.

Costal (KOSS) Pertaining to a rib.

Cryptorchidism (krip-TOR-ki-dizm) The condition in which the testes fail to descend into the scrotum.

Cranial nerve One of 12 pairs of nerves that leave the cranial bones and containing the cranial cavity.

Cranial (KRA-ne-al) A cavity within the cranial cavity.

Cranial nerve One of 12 pairs of nerves that leave the cranial bones and containing the cranial cavity.

Cramp A spasmodic, usually painful contraction of a muscle.

Cranial (KRA-ne-al) A cavity within the cranial cavity.

Cranial nerve One of 12 pairs of nerves that leave the cranial bones and containing the cranial cavity.

Crista (KRIS-ta) A crest or ridged structure. A section of the diaphragm which is directed toward a near object being viewed in order to produce a single image.

Crossing-over An exchange of genes among chromatids and is one factor that results in genetic variation of progeny.

Crus (KRUSS) A scroll-like bone found in the skull.

Cuff (KUF) Pertaining to a rib.

Cupula (KU-pu-la) A mass of gelatinous material in the ampulla of a semicircular canal.

Corpus albicans (KOR-pus AL-bi-kanz) A white fibrous patch in the ovary that forms after the corpus luteum regresses.

Corpus luteum (LOO-te-um) A yellowish body in the ovary formed when a follicle has discharged its secondary oocyte; secretes estrogens, progesterone, relaxin, and inhibin.

Corpus striatum (str-A-tum) An area in the interior of each cerebral hemisphere composed of the caudate and putamen of the basal ganglia and white matter of the internal capsule, arranged in a striated manner.

Cortex (KOR-teks) An outer layer of an organ. The convoluted layer of gray matter covering each cerebral hemisphere.

Costal (KOSS) Pertaining to a rib.
Demineralization (de-min-er-al-i-zun) Loss of calcium and phosphorus from bones.

Denticle (den-DRT-ik) One type of antigen-presenting cell with long, branched projections that commonly is present in mucosal linings such as the vagina, in the skin (Langerhans cells in the epidermis), and in lymph nodes (follicular dendritic cells).

Dental caries (KA-riz) Gradual demineralization of the enamel and dentin of a tooth that may invade the pulp and alveolar bone. Also called tooth decay.

Denticulate (den-TIK-i-lait) Finely toothed or serrated; characterized by a series of small, pointed projections.

Dentin (DEN-tin) The bony tissues of a tooth enclosing the pulp cavity.

Dentition (den-TI-shun) The eruption of teeth. The number, shape, and arrangement of teeth.

Deoxyribonucleic acid (DNA) A nucleic acid constructed of nucleotides consisting of one of four bases (adenine, cytosine, guanine, or thymine), deoxyribose, and a phosphate group; encoded in the nucleotides is genetic information.

Depression (de-PRESH-un) Movement in which the contents leak out.

Dermal papilla (pa-PILL-a) Fingerlike projection from the neural crest that represents the origin of the inguinal canal.

Dermatology (der-MOL-o-jy) The medical specialty dealing with diseases of the skin.

Dermatome (DER-ma-tom) The cutaneous area developed from one embryonic spinal cord segment and receiving most of its sensory innervation from one spinal nerve. An instrument for incising the skin or cutting thin transplants of skin.

Dermis (DER-mis) A layer of dense irregular connective tissue lying deep to the epidermis.

Descending colon (KÖ-lon) The part of the large intestine descending from the left colic (splenic) flexure to the level of the left iliac crest.

Detrusor (de-TROO-ser) Smooth muscle that forms the wall of the urinary bladder.

Developmental biology The study of development of an organism; having two haploid sets of chromosomes, one each from the mother and father.

Dermoid (der-moid) A cystic mass of skin and underlying tissues that commonly is present in mucosal linings such as the vagina, in the skin (Langerhans cells in the epidermis), and in lymph nodes (follicular dendritic cells).

Diastolic (dī-ás-to-lık) In the cardiac cycle, the phase of relaxation or dilation of the heart muscle, especially of the ventricles.

Diastolic (dī-as-TOL-ik) blood pressure The force exerted by blood on arterial walls during ventricular relaxation; the lowest blood pressure measured in the large arteries, normally about 80 mmHg in a young adult.

Diencephalon (dī-en-sef-a-lon) A part of the brain consisting of the thalamus, hypothalamus, and epithalamus.

Diffusion (dī-FU-zhun) A passive process in which there is a net or greater movement of molecules or ions from a region of high concentration to a region of low concentration until equilibrium is reached.

Digestion (dī-JES-shun) The mechanical and chemical breakdown of food into simple molecules that can be absorbed and used by body cells.

Dilate (Dī-lait) To expand or swell.

Diploid (DIP-loid) Having the number of chromosomes characteristic of somatic cells of an organism; having two haploid sets of chromosomes, one each from the mother and father. Symbolized 2n.

Diploid (DIP-loid) Having the number of chromosomes characteristic of somatic cells of an organism; having two haploid sets of chromosomes, one each from the mother and father. Symbolized 2n.

Direct motor pathways Collections of upper motor neurons with cell bodies in the motor cortex that project axons into the spinal cord, where they synapse with lower motor neurons or interneurons in the anterior horns. Also called the pyramidal pathways.

Disease Any change from a state of health.

Dislocation (dis-JÖ-KA-shun) Displacement of a bone from a joint with tearing of ligaments, tendons, and articular capsules. Also called luxation (luk-AS-shun).

Dissect (di-SEKT) To separate tissues and parts of a cadaver or an organ for anatomical study.

Distal (DIS-tal) Farther from the attachment of a limb to the trunk; farther from the point of origin or attachment.

Diuretic (dī-yü-RET-ik) A chemical that increases urine volume by decreasing reabsorption of water, usually by inhibiting sodium reabsorption.

Divergence (di-VER-jens) A synaptic arrangement in which the synaptic end bulbs of one presynaptic neuron terminate on several postsynaptic neurons.

Divergent (dī-ver-jent) Deviating from a straight line; having different points of departure.

Dorsal ramus (DÖR-sal) A branch of a spinal nerve containing sensory axons supplying the muscles, skin, and bones of the posterior part of the head, neck, and trunk.

Dorsiflexion (dōr-fleks-shun) A movement in which the foot is moved in the direction of the dorsum (upper surface).

Duct of Santorini (dūkt) A small vessel connecting the pulmonary trunk with the aorta; found only in the fetus.

Ductus arteriosus (dūkt) A small vessel connecting the pulmonary trunk with the aorta; found only in the fetus.

Ductus arteriosus (dūkt) A small vessel connecting the pulmonary trunk with the aorta; found only in the fetus.

Ductus arteriosus (dūkt) A small vessel connecting the pulmonary trunk with the aorta; found only in the fetus.
Ductus (vas) deferens (DEF-er-ens) The duct that carries sperm from the epididymis to the ejaculatory duct. Also called the seminal duct.

Ductus epididymis (ep-‘i-DID-i-mis) A tightly coiled tube inside the epididymis, distinguished into a head, body, and tail, in which sperm undergo maturation.

Ductus venosus (ve-NO-sus) A small vessel in the fetus that helps the circulation bypass the liver.

Duodenal (doo-‘o-DÉ-nal) gland Gland in the submucosa of the duodenum that secretes an alkaline mucus to protect the lining of the small intestine from the action of enzymes and to help neutralize the acid in chyme. Also called a Brunner’s (BRUN-erz) gland.

Duodenal papilla (pa-PILL-uh) An elevation on the duodenal mucosa that receives the hepatopancreatic ampulla (ampulla of Vater).

Duodenum (doo-‘o-DÉ-num or doo-OD-e-num) The first 25 cm (10 in.) of the small intestine, which connects the stomach and the ileum.

Dura mater (DOO-ra MAH-ter) The outermost of the three meninges (coverings) of the brain and spinal cord.

Dynamic equilibrium (é-kwí-LIB-re-úm) The maintenance of body position, mainly the head, in response to sudden movements such as rotation.

Dysmenorrhea (dis-‘men-Ö-RÉ-uh) Painful menstruation.

Dysplasia (dis-PLA-ze-uh) Change in the size, shape, or formation of structures such as muscles, nerves, and glands.

Dyspnea (DISP-ne-uh) Shortness of breath; painful or labored breathing.

E

Ectoderm The primary germ layer that gives rise to the nervous system and the epidermis of skin and its derivatives.

Ectopic (ek-TOP-ik) Out of the normal location, as in ectopic pregnancy.

Edema (ed-É-ma) An abnormal accumulation of interstitial fluid.

Effector (ef-EK-tor) An organ of the body, either a muscle or a gland, that is innervated by somatic or autonomic motor neurons.

Efferent arteriole (EF-er-ent ar-TE-re-ó) A vessel of the renal vascular system that carries blood from a glomerulus to a peritubular capillary.

Efferent (EF-er-ent) ducts A series of coiled tubes that transport sperm from the rete testis to the epididymis.

Ejaculation (é-jak-‘o-LÁ-shun) The reflex ejection or expulsion of semen from the penis.

Ejaculatory (é-JAK-‘o-la-tó-re) duct A tube that transports sperm from the ductus (vas) deferens to the prostate urethra.

Elasticity (é-las-TIS-i-té) The ability of tissue to return to its original shape after contraction or extension.

Electrocardiogram (é-lek-‘tró-KAR-dé-ó-gram) (ECG or EKG) A recording of the electrical changes that accompany the cardiac cycle that can be detected at the surface of the body; may be resting, stress, or ambulatory.

Elevation (é-lá-VÁ-shun) Movement in which a part of the body moves superiorly.

Embolus (EM-bó-lus) A blood clot, bubble of air or fat from broken bones, mass of bacteria, or other debris or foreign material transported by the blood.

Embryo (EM-bra-ó) The young of any organism in an early stage of development; in humans, the developing organism from fertilization to the end of the eighth week of development.

Embryoblast A region of cells of a blastocyst that differentiates into the three primary germ layers—ectoderm, mesoderm, and endoderm—from which all tissues and organs develop; also called an inner cell mass.

Embryology (em-‘bra-Ö-LÁ-juh) The study of development of the fertilized egg to the end of the eighth week of development.

Emesis (EM-é-sis) Vomiting.

Emigration (em-‘i-GRÁ-shun) Process whereby white blood cells (WBCs) leave the bloodstream by rolling along the endothelium, sticking to it, and squeezing between the endothelial cells. Adhesion molecules help WBCs stick to the endothelium. Also known as migration or extravasation.

Emission (é-MISH-un) Propulsion of sperm into the urethra due to peristaltic contractions of the ducts of the testes, epididymides, and ductus (vas) deferens as a result of sympathetic stimulation.

Emphysema (em-‘fi-SE-ma) A lung disorder in which alveolar walls disintegrate, producing abnormally large air spaces and loss of elasticity in the lungs; typically caused by exposure to cigarette smoke.

Emulsification (é-mul-‘si-fi-KÁ-shun) The dispersion of large lipid globules into smaller, uniformly distributed particles in the presence of bile.

Enamel (en-‘NAM-ehl) The hard, white substance covering the crown of a tooth.

Endocardium (en-dó-KAR-dium) The layer of the heart wall, composed of endothelium and smooth muscle, that lines the inside of the heart and covers the valves and tendons that hold the valves open.

Endocrine (EN-dó-kron) gland A gland that secretes hormones into interstitial fluid and then the blood; a ductless gland.

Endocrinology (en-‘dó-kri-NOL-ov-juh) The science concerned with the structure and functions of endocrine glands and the diagnosis and treatment of disorders of the endocrine system.

Endocytosis (en-‘dó-sís-tó-sis) The uptake into a cell of large molecules and particles in which a segment of plasma membrane surrounds the substance, encloses it, and brings it in; includes phagocytosis, pinocytosis, and receptor-mediated endocytosis.

Endoderm (EN-dó-derm) A primary germ layer of the developing embryo; gives rise to the gastrointestinal tract, urinary bladder, urethra, and respiratory tract.

Endodontics (en-’dó-DON-tik스) The branch of dentistry concerned with the prevention, diagnosis, and treatment of diseases that affect the pulp, root, periodontal ligament, and alveolar bone.

Endolphym (EN-dó-lim-fuh) The fluid within the membranous labyrinth of the internal ear.

Endometriosis (en-’dó-ME-tré-oh-sis) The growth of endometrial tissue outside the uterus.

Endometrium (en-’dó-MÉ-tré-um) The mucous membrane lining the uterus.

Endosmosis (en-’dó-MIZ-uh) Inagination of the perimysium separating each individual muscle fiber (cell).

Endoneurium (en-’dó-NOO-re-um) Connective tissue wrapping around individual nerve axons.

Endoplastic reticulum (en-’dó-PLAS-mik re-TIK-uh-um) (ER) A network of channels running through the cytoplasm of a cell that serves in intracellular transportation, support, storage, synthesis, and packaging of molecules. Portions of ER where ribosomes are attached to the outer surface are called rough ER; portions that have no ribosomes are called smooth ER.

End organ of Ruffini See Type II cutaneous mechanoreceptor.

Endosteam (en-DÓ-Š-túm) The membrane that lines the medullary (marrow) cavity of bones, consisting of osteogenic cells and scattered osteoclasts.

Endothelium (en-’dó-THÉ-le-um) The layer of simple squamous epithelium that lines the cavities of the heart, blood vessels, and lymphatic vessels.

Enteric (EN-ter-ik) nervous system The part of the nervous system that is embedded in the submucosa and muscularis of the gastrointestinal (GI) tract; governs motility and secretions of the GI tract.

Enteroneodocrine (en-ter-ö-EN-dó-kron) cell A cell of the mucosa of the gastrointestinal tract that secretes a hormone that governs function of the GI tract; hormones secreted include gastrin, cholecystokinin, glucose-dependent insulinotropic peptide (GIP), and secretin.

Enzyme (EN-zim) A substance that accelerates chemical reactions; an organic catalyst, usually a protein.

Eosinophil (é-ó-SIN-o-fil) A type of white blood cell characterized by granules that stain red or pink with acid dyes.

Ependymal (ep-EN-de-mal) cells Neuronal cells that cover choroid plexuses and produce cerebrospinal fluid (CSF); they also line the ventricles of the brain and probably assist in the circulation of CSF.

Epidermidics (ep-‘i-KAR-dé-um) The thin outer layer of the heart wall, composed of serous tissue and mesothelium. Also called the visceral pericardium.

Epidemiology (ep-‘i-de-mé-OL-oh-jé) Study of the occurrence and transmission of diseases and disorders in human populations.
**Epidermis** (ep`-i-DERM-iss) The superficial, thinner layer of skin, composed of keratinized stratified squamous epithelium.

**Epididymis** (ep`-i-DID-i-mis) A comma-shaped organ that lies along the posterior border of the testis and contains the ductus epididymis, in which sperm undergo maturation. **Plural is epididymides** (ep`-i-DI-DIM-i-dez).

**Epidural** (ep`-i-DOO-ral) **space** A space between the spinal dura mater and the vertebral canal, containing areolar connective tissue and a plexus of veins.

**Epiglottis** (ep`-i-GLOT-is) A large, leaf-shaped piece of cartilage lying on top of the larynx, attached to the thyroid cartilage; its unattached portion is free to move up and down to cover the glottis (vocal folds and rima glottidis) during swallowing.

**Epimyositis** (ep`-i-MIZ-e-tum) Fibrous connective tissue surrounding muscles.

**Epinephrine** (ep`-e-NIF-rin) Hormone secreted by the adrenal medulla that produces actions similar to those that result from sympathetic stimulation. Also called **adrenaline** (a-DREN-a-line).

**Epineurium** (ep`-i-NOO-re-um) The superficial connective tissue covering around an entire nerve.

**Epiphysis** (e-PIF-i-sis) The end of a long bone, usually larger in diameter than the shaft (diaphysis).

**Epiphysis cerebri** (FA-laks cer-e-bre¯) A fold of the dura mater attached to the occipital bone in the posterior cranial fossa and projecting inward between the two cerebellar hemispheres.

**Epistaxis** (ep` i-STAK-sis) Loss of blood from the nose due to trauma, infection, allergy, neoplasm, and bleeding disorders. Also called **nosebleed**.

**Epithalamus** (ep`-i-THAL-a-nus) Part of the diencephalon superior to and posterior to the thalamus, comprising the pineal gland and associated structures.

**Epithelial** (ep`-i-THE-uhl) **tissue** The tissue that forms the innermost and outermost surfaces of body structures and organs.

**Eponychium** (ep`-o-NIK-e-um) Narrow band of stratum corneum at the proximal border of a nail that extends from the margin of the nail wall. Also called the **cuticle**.

**Erectile dysfunction** Failure to maintain an erection long enough for sexual intercourse. Also known as **impotence** (IM-poh-tens).

**Erection** (er-EK-shun) The enlarged and stiff state of the penis or clitoris resulting from the engorgement of the spongy erectile tissue with blood.

**Erector of the T-A-shun** The forceful expulsion of gas from the stomach. Also called **belching**.

**Erythema** (er-e-THé-ma) Skin redness usually caused by dilation of the capillaries.

**Erythrocyte** (e-RITH-ro-st) A mature red blood cell.

**Erythropoietin** (e-ri-thRO-poye-tin) A hormone released by the juxtaglomerular cells of the kidneys that stimulates red blood cell production.

**Esophagus** (es-OP-a-gus) The hollow muscular tube that connects the pharynx and the stomach.

**Excretion** (eks-KRE-shun) The process of eliminating waste products from the body; also the products excreted.

**Excessive exhalation** (eks-sæ-eks) A forceful expiration against a closed glottis, as from a sudden expenditure of energy.

**Exhalation** (eks-HEAL-a-shun) Breathing out; expulsion of air from the lungs into the atmosphere. Also called **expiration**.

**Excessive extensibility** (eks-HEKS-i-ti-AL) The ability of muscle tissue to stretch when it is pulled.

**Expression** (eks-PRES-she-AL) Secretion of milk from the mammary gland.

**Extensibility** (eks-TEN-i-ti-AL) The ability of musculoskeletal elements to lengthen or stretch. Also called **elasticity**.

**Extension** (eks-TEN-shun) An increase in the angle between two bones; restoring a body part to its anatomical position after flexion.

**Falx cerebri** (FALKS cer-e-bre¯) A fold of the dura mater extending deep into the longitudinal fissure between the two cerebral hemispheres.

**Fascia** (FA-she-ah) The outermost layer of skin, composed of keratinized stratified squamous epithelium.

**Fertility** (fer-ELE-ter) Pertaining to the ability of a living organism to produce offspring.

**Fetus** (FE-nus) Material discharged from the rectum and made up of bacteria, excretions, and food residue. Also called **stool**.

**Female reproductive cycle** General term for the ovarian and uterine cycles, the hormonal changes that accompany them, and cyclic changes in the breasts and cervix; includes changes in the endometrium of a nonpregnant female that prepares the lining of the uterus to receive a fertilized ovum. Less correctly termed the **menstrual cycle**.

**Fertilization** (fer-ELE-ter-ee-uh) Penetration of a secondary oocyte by a sperm cell, meiotic division of secondary oocyte to form an ovum, and subsequent union of the nuclei of the gametes.

**Fetal circulation** The cardiovascular system of the fetus, including the placenta and special blood vessels involved in the exchange of materials between fetus and mother.

**Fetus** (FE-nus) In humans, the developing organism in utero from the beginning of the third month to birth.

**Fever** An elevation in body temperature above the normal temperature of 37 °C (98.6 °F) due to a resetting of the hypothalamic thermostat.

**Fibroblast** (FIB-ro-blast) A large, flat cell that secretes most of the extracellular matrix of areolar and dense connective tissues.

**Fibrous** (FIB-ros) **joint** A joint that allows little or no movement, such as a suture or a syndesmosis.

**Fibrous tunic** (too-nik) The superficial coat of the eyeball, made up of the posterior sclera and the anterior cornea.

**Fight-or-flight response** The effects produced upon stimulation of the sympathetic division of the autonomic nervous system.
Filiform papilla (FIL-i-form pa-PIL-a) One of the conical projections that are distributed in parallel rows over the anterior two-thirds of the tongue and lack taste buds.

Filtration (fil-TRÁ-shun) The flow of a liquid through a filter (or membrane that acts like a filter) due to a hydrostatic pressure; occurs in capillaries due to blood pressure.

F lens (F-lum ter-mi-NAL-e) Non-branching tube from carpal bones, tarsal bones, and the scapula. Also called the arthrodial (ar-THRO-da-al) joint.

Glomerular (glô-MER-ü-lar) A double-walled globule at the proximal end of a nephron that encloses the glomerular capillaries. Also called Bowman’s (BO-manz) capsule.

Glomerular filtrate (glô-MER-ü-lar FIL-trât) The fluid produced when blood is filtered by the filtration membrane in the glomeruli of the kidneys.

Glomerular filtration The first step in urine formation in which substances in blood pass through the filtration membrane and the filtrate enters the proximal convoluted tubule of a nephron.

Glomerulus (glô-MER-ü-lus) A rounded mass of capillaries in the glomeruli of the kidneys.

Glottis (GLOT-is) The vocal folds (true vocal cords) in the larynx plus the space between them (rima glottidis).

Glucagon (GLOO-gan) A hormone produced by the alpha cells of the pancreatic islets (islets of Langerhans) that increases blood glucose level.

Glucocorticoids (gloo-kó-KOR-ty-koyds) Hormones secreted by the cortex of the adrenal gland, especially cortisol, that influence glucose metabolism.

Glucose (GLOO-kôs) A hexose (six-carbon sugar), C6H12O6, that is a major energy source for the production of ATP by body cells.

Glucosuria A condition in which substances in blood pass through the filtration membrane and the filtrate enters the proximal convoluted tubule of a nephron.

Genotype (JE-nô-tip) The genetic makeup of an individual; the combination of alleles present at one or more chromosomal locations, as distinguished from the appearance, or phenotype, that results from those alleles.

Geriatrics (jer-i-ÁT-riks) The branch of medicine devoted to the medical problems and care of elderly persons.

Gestation (jes-TÄ-shun) The period of development from fertilization to birth.

Gingiva (jin-GI-vä) Gums. They cover the alveolar processes of the mandible and maxilla and extend slightly into each socket.

Gland A structure that produces and secretes substances; e.g., the salivary gland or the pancreas.

Glandular A gland or secreting tissue, especially a lacrimal gland.

Globe (GLOB) The transparent sphere covering the eye and containing the ocular contents.

Glossary G11
GLOSSARY

G12

Goiter (GO-yer) An enlarged thyroid gland.

Golgi (GOIL-jé) complex One of the secretory units formed by the Golgi apparatus in which proteins are processed and packaged for transport to other organelles or for secretion.

Gonad (GOH-nad) A gland that produces gametes and hormones; the ovary in the female and the testis in the male.

Gonadotropic hormone Anterior pituitary hormone that affects the gonads.

Gout (GOH-t) Hereditary condition associated with excess uric acid in the blood; the acid crystallizes and deposits in joints, kidneys, and soft tissue.

Gray ramus communicans (GRAY-ramus-koh-MAYN-kaans) A short nerve containing axons of sympathetic ganglia, which axons of the gracile fasciculus terminate.

Gray commissure (GRAY-komishur) A narrow strip of gray matter connecting the lateral gray masses within the spinal cord.

Gray matter Areas in the central nervous system and ganglia containing neuronal cell bodies, dendrites, myelinated axons, axon terminals, and neuroglia; Nissl bodies impart a gray color to the tissue and there is little or no myelin in gray matter.

Gray ramus communicans (RA-mus-koh-MAYN-kaans) A short nerve containing axons of sympathetic ganglia, which axons of the gracile fasciculus terminate.

Grey matter Areas in the central nervous system and ganglia containing neuronal cell bodies, dendrites, myelinated axons, axon terminals, and neuroglia; Nissl bodies impart a gray color to the tissue and there is little or no myelin in gray matter.

Greater omentum (GOH-rey-men-tum) A large fold in the serosa of the stomach that hangs down like an apron anterior to the intestines.

Greater vestibular (VES-tib-ular) glands A pair of glands on either side of the vaginal orifice that open by a duct into the space between the hymen and the labia minora. Also called Bartholin’s (BAR-toh-lin) glands.

Groin (GROYN) The depression between the thigh and the trunk; the inguinal region.

Gross anatomy The branch of anatomy that deals with structures that can be studied without using a microscope. Also called macroscopic anatomy.

Growth An increase in size due to an increase in (1) the number of cells, (2) the size of existing cells as internal components increase in size, or (3) the size of intercellular substances.

Gustatory (gus-TAT-er-ee) Pertaining to taste.

Gynecology (gyn-ee-KOL-ee) The branch of medicine dealing with the study and treatment of disorders of the female reproductive system.

Gynecomastia (gyn-ee-koh-MAS-tuh) Excessive growth (benign) of the male mammary glands due to secretion of estrogens by an adrenal gland tumor (feminizing adenoma).

Gyrus (ji-ruhs) One of the folds of the cerebral cortex of the brain. Plural is gyri (ji-rihs). Also called a convolution.

H

Hair A threadlike structure produced by hair follicles that develops in the dermis. Also called a pilus (PLUSS).

Hair follicle (FOH-lee-kul) Structure composed of epithelium and surrounding the root of a hair from which hair develops.

Hair root plexus (PLEX-us) A network of dendrites arranged around the root of a hair as free or naked nerve endings that are stimulated when a hair shaft is moved.

Hand The terminal portion of an upper limb, including the carpus, metacarpus, and phalanges.

Haplod (HAP-loyd) Having half the number of chromosomes characteristically found in the somatic cells of an organism; characteristic of mature gametes. Symbolized n.

Hard palate (HALD palt) The anterior portion of the roof of the mouth, formed by the maxillae and palatine bones and lined by mucous membrane.

Haustra (HAUS-tra) A series of pouches that characterize the colon; caused by tonic contractions of the teniae coli. Singular is haustrum.

Haversian canal (HA-ver-SYE-an) A small, raised area of cancellous bone that develops into blood vessels and bone vessels.

Hematocrit (he-MAT-o-krith) The percentage of blood made up of red blood cells. Usually measured by centrifuging a blood sample in a graduated tube and then reading the volume of red blood cells and dividing it by the total volume of blood in the sample.

Hematology (HEH-muh-toh-loh-je) Refers to the blood.

Hernia (HER-nee-uh) A protrusion or projection of an organ or part of an organ through a membrane or cavity wall, usually the abdominal cavity.

Herniated (HER-nay-ted) A rupture of an intervertebral disc so that the nucleus pulposus protrudes into the vertebral cavity. Also called a slipped disc.

Hemolytic disease of the newborn A hemolytic anemia of a newborn child that results from the destruction of the infant’s erythrocytes (red blood cells) by antibodies produced by the mother; usually the antibodies are due to an Rh blood type incompatibility. Also called erythroblastosis fetalis (eh-rith-roh-blas-toh-sis-fet-als).

Hemophilia (HEH-moh-FIL-ee-uh) A hereditary blood disorder where there is a deficient production of certain factors involved in blood clotting, resulting in excessive bleeding into joints, deep tissues, and elsewhere.

Hemorrhage (HEH-moh-RAYJ) Bleeding; the escape of blood from blood vessels, especially when the loss is profuse.

Hemorrhoids (HEH-mor-roys) Dilated or varicose blood vessels (usually veins) in the anal region. Also called piles.

Hepatic (HEP-ah-tik) Refers to the liver.

Hepatic duct A duct that receives bile from the bile capillaries. Usually hepatic ducts merge to form the larger right and left hepatic ducts that unite to leave the liver as the common hepatic duct.

Hepatic portal circulation The flow of blood from the gastrointestinal organs to the liver before returning to the heart.

Hepatocyte (HEP-uh-toh-sye) A liver cell.

Hepatopancreatic (HEP-ah-toh-pah-NEE-trik) ampu-lae A small, raised area in the duodenum where the combined common bile duct and main pancreatic duct empty into the duodenum. Also called the ampullae of Vater (VA-ter).

Hernia (HER-nea) The protrusion or projection of an organ or part of an organ through a membrane or cavity wall, usually the abdominal cavity.

Herniated (HER-nay-ted) A rupture of an intervertebral disc so that the nucleus pulposus protrudes into the vertebral cavity. Also called a slipped disc.

Hiatus (hee-AY-tus) An opening; for a foramen.

Hilum (HEE-lum) An area, depression, or pit where blood vessels and nerves enter or leave an organ. Also called a hilus.

Hinge joint A synovial joint in which a convex surface of one bone fits into a concave surface of another bone, such as the elbow, knee, ankle, and interphalangeal joints. Also called a ginglymus (JIN-gly-mus) joint.

Hirsutism (HER-soo-tizm) An excessive growth of hair in females and children, with a distribution similar to that in adult males, due to the conversion of vellus hairs into large terminal hairs in response to higher-than-normal levels of androgens.
Histamine (HIS-täm) Substance found in many cells, especially mast cells, basophils, and platelets, that is released when the cells are injured; results in vasodilation, increased permeability of blood vessels, and constriction of bronchioles.

Histology (his-TOL-oh-jé) Microscopic study of the structure of tissues.

Holocrine (HÖ-ler-kin) gland A type of gland in which entire secretory cells, along with their accumulated secretions, make up the secretory product of the gland, as in the sebaceous (oil) glands.

Homeostasis (hö-MÖE-stuh-sis) The condition in which the body’s internal environment remains relatively constant within physiological limits.

Homologous chromosomes Two chromosomes that belong to a pair. Also called homologs.

Hormone (HÖR-mön) A secretion of endocrine cells that alters the physiological activity of target cells of the body.

Horn (HÖRn) An area of gray matter (anterior, lateral, or posterior) in the spinal cord.

Human chorionic gonadotropin (kö-rih-ON-ik go-NAH-duh-troh-pin) (hCG) A hormone produced by the developing placenta that maintains the corpus luteum.

Human chorionic somatomammotropin (so-MÖ-muh-mam-oh-troh-pin) (hCS) Hormone produced by the chorion of the placenta that stimulates the corpus luteum.

Hyaluronic acid (hi-ALUR-uh-nik) A viscous, amorphous extracellular material that binds cells together, lubricates joints, and maintains the shape of the eyeballs.

Hymen (HY-men) A thin fold of vascularized mucous membrane at the vaginal orifice.

Hypercortisolism (hi-per-kor- ti-SOHL-uh-siz-uhm) The process by which the anterior pituitary reduces the secretion of adrenocorticotropic hormone from the anterior pituitary.

Inherit (IN-her-it) The process by which genetic information from parents is transmitted to the offspring.

Hyperventilation (hi-per-ven-ti-LÁ-shun) A rate of inhalation and exhalation higher than that required to maintain a normal partial pressure of carbon dioxide in the blood.

Hypnochium (hi-pö-NIK-ë-um) Free edge of the fingernail.

Hypophyseal fossa (hi-pö-FIZ-ë-al) Fossa.

Hypopituitary (hi-pö-sit-ee-uh-) Hypopituitarism; a condition that results from inadequate thyroid hormones, growth hormone, and adrenocorticotropic hormone, also known as hypothyroidism.

Hypothalamus (hi-po-THAL-uh-mus) A portion of the brain that regulates bodily functions such as hunger, thirst, body temperature, and sleep.

Hypotonia (hi-pö-TOH-ni-uh) Low muscle tone in which muscles appear flaccid.

Hypoxia (hi-PÖKS-ë-uh) Lack of adequate oxygen at the tissue level.

Ileocecal valve (i-LEE-oh-seh-kal) The valve at the junction of the ileum and cecum.

Immunity (im-NI-tee) Immunologic response to an antigen that provides resistance to future infections.

Inhibit (IN-hib-it) To prevent the action of a hormone, an enzyme, or a drug; to stop the movement of a substance.

Inhibiting hormone Hormone secreted by the hypothalamus that inhibits the secretion of another hormone from the anterior pituitary.

Insertion (in-SER-shun) The attachment of a muscle tendon to a movable bone or the end opposite the origin.

Insula (IN-soo-lah) A triangular area of the cerebral cortex that lies deep within the lateral cerebral tissue, under the parietal, frontal, and temporal lobes.
**G14 GLOSSARY**

**Insulin** (IN-soo-lin) A hormone produced by the beta cells of a pancreatic islet (islet of Langerhans) that decreases the blood glucose level.

**Integrins** (IN-te-grinz) A family of transmembrane glycoproteins in plasma membranes that function in cell adhesion; they are present in hemidesmosomes, which anchor cells to a basement membrane, and they mediate adhesion of neutrophils to endothelial cells during emigration.

**Intercalated** (in-TER-ka-là t-ed) disc An irregularly transverse thickening of sarcolemma that contains desmosomes, which hold cardiac muscle fibers (cells) together, and gap junctions, which aid in conduction of muscle action potentials from one fiber to the next.

**Intercostal** (in-tek-sot-al) nerve A nerve supplying a muscle located between the ribs.

**Intermediate** Between two structures, one of which is medial and one of which is lateral.

**Intermediate filament** Protein filament, ranging from 8 to 12 nm in diameter, that may provide structural reinforcement, hold organelles in place, and give shape to a cell.

**Internal** Away from the surface of the body.

**Internal capsule** A large tract of projection fibers lateral to the thalamus that is the major connection between the cerebral cortex and the brain stem and spinal cord; contains axons of sensory neurons carrying auditory, visual, and somatic sensory signals to the cerebral cortex plus axons of motor neurons descending from the cerebral cortex to the thalamus, subthalamus, brain stem, and spinal cord.

**Internal ear** The inner ear or labyrinth, lying inside the temporal bone, containing the organs of hearing and balance.

**Internal nares** (NA-rez) The two openings posterior to the nasal cavities opening into the nasopharynx. Also called the choanae (kó-Á-né).

**Internal respiration** The exchange of respiratory gases between blood and body cells. Also called tissue respiration.

**Interneurons** (in-ter-NOO-ronz) Neurons whose axons extend only for a short distance and contact nearby neurons in the brain, spinal cord, or a ganglion; they comprise the vast majority of neurons in the body.

**Interoceptor** (IN-ter-oh-sep-tor) Sensory receptor located in blood vessels and viscera that provides information about the body’s internal environment.

**Interphase** (IN-ter-fa-z) The period of the cell cycle in which a cell is not engaged in mitosis or meiosis; in interphase, the chromosomes are replicated and the cell grows.

**Interstitial** (in’-ter-STISH-al) fluid The portion of extracellular fluid that fills the microscopic spaces between the cells of tissues; the internal environment of the body. Also called intercellular or tissue fluid.

**Intestinal growth** Growth from within, as in the growth of cartilage. Also called endogenous (en-DOJ-e-nus) growth.

**Interventricular** (in’-ter-ven-TRIK-u-lar) foramen A narrow, oval opening through which the lateral ventricles of the brain communicate with the third ventricle. Also called the foramen of Monro.

**Intervertebral** (in’-ter-VER-te-bral) disc A pad of fibrocartilage located between the bodies of two vertebrae.

**Intestinal gland** A gland that opens onto the surface of the intestinal mucosa and secretes digestive enzymes. Also called a crypt of Lieberkühn (LÉ-bür-kuhn).

**Intracellular** (in-ter-cellu-lar) fluid (ICF) Fluid located within cells.

**Intrafusal** (in-tra-FÜ-sal) fibers Three to ten specialized muscle fibers (cells), partially enclosed in a spindle-shaped connective tissue capsule, that make up a muscle spindle.

**Intramembranous ossification** (in’-tra-MEM-bra-nus os’-i-fi-kä-shun) The method of bone formation in which the bone is formed directly in mesenchyme arranged sheet-like layers that resemble membranes.

**Intracranial** (in-tra-KRA-né-al) pressure (IOP) Pressure in the eyeball, produced mainly by aqueous humor.

**Intrinsic factor** (IF) A glycoprotein, synthesized and secreted by the parietal cells of the gastric mucosa, that facilitates vitamin B₁₂ absorption in the small intestine.

**Invagination** (in-vaj’-i-nä-shun) The pushing of the wall of a cavity into the cavity itself.

**Inversion** (in-ver-zhun) The movement of the sole of the foot in which the plantar surface is turned upward.

**Investiture** (IN-vest-ùr-ú-je) The study of the movement of body parts.

**Intestine** (in-sten) One of the paired reddish organs located in the lumbar region that regulates the composition, volume, and pressure of blood and produces urine.

**Intestine stone** A solid mass, usually consisting of calcium oxalate, uric acid, or calcium phosphate crystals, that may form in any portion of the urinary tract. Also called a renal calculus.

**Intercostal en-thesiome** Interconnection between bone cells of the distal convoluted tubule adjacent to the afferent and efferent arteriole and juxtaglomerular cells (modified cells of the afferent and sometimes efferent arteriole); secretes renin when blood pressure starts to fall.

**Intestine stone** A solid mass, usually consisting of calcium oxalate, uric acid, or calcium phosphate crystals, that may form in any portion of the urinary tract. Also called a renal calculus.

**Keratin** (KER-a-tin) An insoluble protein found in the hair, nails, and other keratinized tissues of the epidermis.

**Keratinocyte** (ker-a-TIN-o-sit) The most numerous of the epidermal cells; produces keratin.

**Kidney** (KID-ne) One of the paired reddish organs located in the lumbar region that regulates the composition, volume, and pressure of blood.

**Kidney stone** A solid mass, usually consisting of calcium oxalate, uric acid, or calcium phosphate crystals, that may form in any portion of the urinary tract. Also called a renal calculus.

**Kinesiology** (kines-ology) Study of the movement of body parts.

**Kinetochrome** (kiNET-oh-kor) Protein complex attached to the outside of a centromere to which kinetochore microtubules attach.

**Kupffer’s cell** See Kupffer’s reticuloendothelial cell.

**Kyphosis** (ki-FÖ-sis) An exaggeration of the thoracic curve of the vertebral column, resulting in a “round-shouldered” appearance. Also called hunchback.

**Labial frenulum** (la-bí-lím) A fold of mucous membrane between the inner surface of the lip and the gums.

**Labia majora** (la-bí-a ma-JÖ-ra) Two longitudinal folds of skin extending downward and backward from the mons pubis of the female.

**Labia minora** (la-bí-a min-OR-a) Two small folds of mucous membrane lying medial to the labia majora of the female.

**Labor** The process of giving birth in which a fetus is expelled from the uterus through the vagina.
Labyrinth (LAB-irinth) Intricate communicating passageway, especially in the inner ear.

Lacrimal canal A duct, one on each eyelid, beginning at the punctum at the medial margin of an eyelid and conveying tears medially into the nasolacrimal sac.

Lacrimal gland Secretory organs located at the superior anterolateral portion of each orbit, that secrete tears into excretory ducts that open onto the surface of the conjunctiva.

Lacrimal sac The superior expanded portion of the nasolacrimal duct that receives the tears from a lacrimal canal.

Lactation (lak-TA-shun) The secretion and ejection of milk from the mammary glands.

Lacteal (LAK-te¯-al) A lymphatic vessel that transports chyle from the intestinal villi to the lymphatic system.

Lactin (LAK-te¯-in) An organol that attaches bone to bone.

Leydig (LI¯-dig) A type of cell that secretes testosterone, located in the connective tissue between seminiferous tubules in a mature testis. Also known as interstitial cell of Leydig or interstitial endocrinocyte.

Ligament (LIG-a-ment) Dense regular connective tissue that attaches bone to bone.

Lipid (LI-pid) An organic compound composed of carbon, hydrogen, and oxygen that is usually insoluble in water, but soluble in alcohol, ether, and chloroform.

Lipid bilayer Arrangement of phospholipid, glycolipid, and cholesterol molecules in two parallel sheets in which the hydrophilic “heads” face outward and the hydrophobic “tails” face inward; found in cellular membranes.

Lipoprotein (lip¯-o-PRÖ-tén) One of several types of particles containing lipids (cholesterol and triglycerides) and proteins that make it water soluble for transport in the blood; high levels of low-density lipoproteins (LDLs) are associated with increased risk of atherosclerosis, whereas high levels of high-density lipoproteins (HDLs) are associated with decreased risk of atherosclerosis.

Liver Large organ under the diaphragm that occupies most of the right hypochondriac region and part of the epigastria region. Functionally, it produces bile and synthesizes most plasma proteins; interconverts nutrients; detoxifies substances; stores glycogen, iron, and vitamins; and carries phosphocytosis of worn-out blood cells and bacteria; and helps synthesize the active form of vitamin D.

Long-term potentiation (LTP) Prolonged, enhanced synaptic transmission that occurs at certain synapses within the hippocampus of the brain; believed to underlie some aspects of memory.

Lordosis (lor-DO-sis) An exaggeration of the lumbar curve of the vertebral column. Also called hollow back.

Lower limb The appendage attached at the pelvic (hip) girdle, consisting of the thigh, knee, leg, ankle, foot, and toes. Also called lower extremity.

Lumen (LOO-men) The space within an artery, vein, intestine, renal tubule, or other tubular structure.

Lungs Main organs of respiration that lie on either side of the heart in the thoracic cavity.

Lymph (LIMF) Fluid confined in lymphatic vessels and flowing through the lymphatic system until it is returned to the blood.

Lymph node An oval or bean-shaped structure located along lymphatic vessels.

Lymphatic (lim-FAT-ik) A network of reticular tissue that contains large numbers of lymphocytes.

Lymphatic vessel A large vessel that collects lymph from lymphatic capillaries and converges with other lymphatic vessels to form the thoracic and right lymphatic ducts.

Lymphocyte (LIM-fö-sit) A type of white blood cell that helps carry cell-mediated and antibody-mediated immune responses; found in blood and in lymphatic tissues.

Lysosome (LI-sö-söm) An organelle in the cytoplasm of a cell, enclosed by a single membrane and containing powerful digestive enzymes.

Lysozyme (LI-sö-zim) A bacterialid enzyme found in tears, saliva, and perspiration.

M

Macrophage (MAK-rö-faj) Phagocytic cell derived from a monocyte; may be fixed or wandering.

Macula (MAK-ü-la) A discolored spot or a colored area. A small, thickened region on the wall of the utricle and saccule that contains receptors for static equilibrium.

Macula lutea (MAK-ü-late) The yellow spot in the center of the retina.

Major histocompatibility (MHC) antigens Surface proteins on white blood cells and other nucleated cells that are recognized by T lymphocytes and the major histocompatibility complex (MHC) on the surface of other cells.
cells that are unique for each person (except for identical siblings); used to type tissues and help prevent rejection of transplanted tissues. Also known as human leukocyte antigens (HLA).

Malignant (ma-LIG-nant) Referring to diseases that tend to become worse and cause death, especially the invasion and spreading of cancer.

Mammary (MAM-ar-é) gland Modified sudoriferous (sweat) gland of the female that produces milk for the nourishment of the young.

Mammillary (MAM-i-lar-é) bodies Two small rounded bodies on the inferior aspect of the hypotalamus that are involved in reflexes related to the sense of smell.

Marrow (MAR-ó) Soft, spongelike material in the cavities of bone. Red bone marrow produces blood cells; yellow bone marrow contains adipose tissue that stores triglycerides.

Mast cell (MAST) A cell found in areolar connective tissue that releases histamine, a dilator of small blood vessels, during inflammation.

Mastication (mas'-ti-KÁ-shun) Chewing.

Maternal (MAT-er-AL) Nearer the midline of the body

Medial (ME-de-al) Nearer the midline of the body or a structure.

Medial lemniscus (lem-NIS-kus) A white matter tract of the brain and spinal cord, called the dura mater, that carries impulses for the sensations of proprioception, fine touch, vibration, hearing, and equilibrium.

Medial plane A vertical plane dividing the body into right and left halves. Situated in the midline.

Mediastinum (me'-di-as-TIN-num) The anatomical region on the thoracic cavity between the pleurae of the lungs that extends from the sternum to the vertebral column and from the first rib to the diaphragm.

Medulla (med'-OOL-la) An inner layer of an organ, such as the medulla of the kidneys.

Medulla oblongata (med'-OOL-la ob-long-GA-ta) The most inferior part of the brain stem. Also termed the medulla oblongata.

Medullary (MED-ú-lar-é) cavity The space within the diaphragm of a bone that contains yellow bone marrow. Also called the marrow cavity.

Medullary rhythmicity (MED-ú-lar-é) area The neurons of the respiratory center in the medulla oblongata that control the basic rhythm of respiration.

Melobiont gland See Tarsal gland.

Meliosis (mi-O-sis) A type of cell division that occurs during the production of gametes, involving two successive nuclear divisions that result in cells with the haploid (n) number of chromosomes.

Melissner (me-ISS-nar) corpuscle A sensory receptor for touch; found in dermal papillae, especially in the palms and soles. Also called a corpuscle of touch.

Melanin (MEL-a-nin) A dark black, brown, or yellow pigment found in some parts of the body such as the skin, hair, and pigmented layer of the retina.

Melanocyte (MEL-a-nó-sit) A pigmented cell, located between or beneath cells of the deepest layer of the epidermis, that synthesizes melanin.

Melanocyte-stimulating hormone (MSH) A hormone secreted by the anterior pituitary that stimulates the dispersion of melanin granules in melanocytes in amphibians; continued administration produces darkening of skin in humans.

Melatonin (mel-a-TÖN-in) A hormone secreted by the pineal gland that helps set the timing of the body’s biological clock.

Membrane A thin, flexible sheet of tissue composed of an epithelial layer and an underlying connective tissue layer, as in an epithelial membrane, or of areolar connective tissue only, as in a synovial membrane.

Membranous labyrinth (mem-BRA-nus LAB-i-rinth) The part of the labyrinth of the internal ear that is located inside the bony labyrinth and separated from it by the perilymph; made up of the semicircular ducts, the saccule, and the utricle, and the cochlear duct.

Memory The ability to recall thoughts; commonly classified as short-term (activated) and long-term.

Menarche (me-NAR-ki) The first menses (menstrual flow) and beginning of ovarian and uterine cycles.

Meninges (me-NING-jez) Three membranes covering the brain and spinal cord, called the dura mater, arachnoid mater, and pia mater. Singular is meninx (me-NINX) (MEN-inks).

Menopause (ME NT-oh-pawz) The termination of the menstrual cycles.

Menstrual (MEHN-struh-ral) cycle A series of changes in the endometrium of a nonpregnant female that prepares the lining of the uterus to receive a fertilized ovum.

Menstruation (men-struh-Á-shun) Periodic discharge of blood, tissue fluid, mucus, and epithelial cells that usually lasts for 5 days; caused by a sudden reduction in estrogen and progesterone. Also called the menstrual phase or menses.

Merkel (MER-kel) cell Type of cell in the epidermis of hairless skin that makes contact with a Merkel (tactile) disc, which functions in touch.

Merkel Disc Saucer-shaped free nerve endings that make contact with Merkel cells in the epidermis and function as touch receptors. Also called a tactile disc.

Mecorecine (MER-ó-krin) gland Gland made up of secretory cells that remain intact throughout the process of formation and discharge of the secretory product, as in the salivary and pancreatic glands.

Mesenchyme (mez-en-ké) An embryonic connective tissue from which all other connective tissues arise.

Mesentery (MEZ-en-ter-é) A fold of peritoneum attaching the small intestine to the posterior abdominal wall.

Mesocolon (mez-’o-KÖ-lon) A fold of peritoneum attaching the colon to the posterior abdominal wall.

Mesoderm The middle primary germ layer that gives rise to connective tissues, blood and blood vessels, and muscles.

Mesothelium (mez-’o-THÉ-lé-um) The layer of simple squamous epithelium that lines serous membranes.

Mesovarium (mez-’o-VAR-é-um) A short fold of peritoneum that attaches an ovary to the broad ligament of the uterus.

Metabolism (me-TAB-é-izm) All the biochemical reactions that occur within an organism, including the synthetic (anabolic) reactions and decomposition (catabolic) reactions.

Metacarpus (me-’TAR-kus) A collective term for the five bones that make up the palm.

Metaphase (MET-a-faz) The second stage of mitosis, in which chromatic pairs line up on the metaphase plate of the cell.

Metaphysis (mee-TAFF-é-isis) Region of a long bone between the diaphysis and epiphysis that contains the epiphyseal plate in a growing bone.

Metarteriole (me-ar-TÉ-re-o-lé) A blood vessel that emerges from an arteriole, traverses a capillary network, and empties into a venule.

Metastasis (me-TASS-ta-sis) The spread of cancer to surrounding tissues (local) or to other body sites (distant).

Metatarsus (me-’TAR-sus) A collective term for the five bones located in the foot between the tarsoles and the phalanges.

Microfilament (mi-kro-FIL-a-ment) Rodlike protein filament about 6 nm in diameter; constitutes contractile units in muscle fibers (cells) and provides support, shape, and movement in nonmuscle cells.

Microglia (mi-KROG-lee-a) Neuroglial cells that carry on phagocytosis.

Microtubule (mi-kro-TOO-bü-lé) Cylindrical protein filament, from 18 to 30 nm in diameter, consisting of the protein tubulin; provides support, structure, and transportation.

Microvilli (mi-kro-VIL-e) Microscopic, fingerlike projections of the plasma membranes of cells that increase surface area for absorption, especially in the small intestine and proximal convoluted tubules of the kidneys.

Micturition (mik-choo-RISH-un) The act of expelling urine from the urinary bladder. Also called urination (u-ri-NAY-shun).

Midbrain The part of the brain between the pons and the diencephalon. Also called the mesencephalon (mez-’en-SEF-ale-lon).

Middle ear A small, epithelial-lined cavity hollowed out of the temporal bone, separated from
the external ear by the eardrum and from the internal ear by a thin bony partition containing the oval and round windows; extending across the middle ear are the three auditory ossicles. Also called the tympanic (tim-PAN-ik) cavity.

Midline An imaginary vertical line that divides the body into equal left and right sides.

Midsagittal plane A vertical plane through the midline of the body that divides the body or organs into equal right and left sides. Also called a median plane.

Mineralocorticoids (min-eral-oh-kor-tik-oidz) A group of hormones of the adrenal cortex that help regulate sodium and potassium balance.

Mitochondrion (mit-oh-kon-dre-on) A double-membraned organelle that plays a central role in the production of ATP; known as the “powerhouse” of the cell. Plural is mitochondria.

Mitosis (mi-tosis) The orderly division of the nucleus of a cell that ensures each new nucleus has the same number and kind of chromosomes as the original nucleus. The process includes the replication of chromosomes and the distribution of the two sets of chromosomes into two separate and equal nuclei.

Miotic spindle Collective term for a football-shaped assembly of microtubules (nonkinetochore, kinetochore, and aster) that is responsible for the movement of chromosomes during cell division.

Modality (mod-a-lar-ee) Any of the specific sensory entities, such as vision, smell, taste, or touch.

Modiolus (muh-DI-o-lus) The central pillar or column of the cochlea.

Monocyte (MON-oh-sit) The largest type of white blood cell, characterized by agranular cytoplasm.

Monounsaturated fat A fatty acid that contains one double covalent bond between its carbon atoms; it is not completely saturated with hydrogen atoms. Plentiful in triglycerides of olive and peanut oils.

Mons pubis (MONZ PÚ-bis) The rounded, fatty prominence over the pubic symphysis, covered by coarse pubic hair.

Morula (MAW-rula) A solid sphere of cells produced by successive cleavage of a fertilized ovum about four days after fertilization.

Motor area The region of the cerebral cortex that governs muscular movement, particularly the precentral gyrus of the frontal lobe.

Motor end plate Region of the sarcolemma of a muscle fiber (cell) that includes acetylcholine (ACh) receptors, which bind ACh released by synaptic end bulbs of somatic motor neurons.

Motor neurons (NOO-rohnz) Neurons that conduct impulses from the brain toward the spinal cord or out of the brain and spinal cord into cranial or spinal nerves to effectors that may be either muscles or glands. Also called efferent neurons.

Motor unit A motor neuron together with the muscle fibers (cells) it stimulates.

Mucosal-associated lymphatic tissue (MALT) Lymphatic nodules scattered throughout the lamina propria (connective tissue) of mucous membranes lining the gastrointestinal tract, respiratory airways, urinary tract, and reproductive tract.

Mucous (MÜ-kus) cell A unicellular gland that secretes mucus. Two types are mucous neck cells and surface mucous cells in the stomach.

Mucous membrane A membrane that lines a body cavity that opens to the exterior. Also called the mucosa (muh-KÖ-sa).

Mucus The thick fluid secretion of goblet cells, mucous cells, mucous glands, and mucous membranes.

Muscarinic (mus-ka-RIN-ik) receptor Receptor for the neurotransmitter acetylcholine found on all effectors innervated by parasympathetic postganglionic axons and on sweat glands innervated by cholinergic sympathetic postganglionic axons; so named because muscarine activates these receptors but does not activate nicotinic receptors for acetylcholine.

Muscle An organ composed of one of three types of muscle tissue (skeletal, cardiac, or smooth), specialized for contraction to produce voluntary or involuntary movement of parts of the body.

Muscle action potential A stimulating impulse that propagates along the sarcolemma and transverse tubules; in skeletal muscle, it is generated by acetylcholine, which increases the permeability of the sarcolemma to cations, especially sodium ions (Na+).

Muscle fatigue (fa-TÉG) Inability of a muscle to maintain its strength of contraction or tension; may be related to insufficient oxygen, depletion of glycogen, and/or lack of lactic acid buildup.

Muscle spindle An encapsulated proprioceptor in a skeletal muscle, consisting of specialized intrafusal muscle fibers and nerve endings; stimulated by changes in length or tension of muscle fibers.

Muscle tone A sustained, partial contraction of portions of a skeletal or smooth muscle in response to activation of stretch receptors or a baseline level of action potentials in the innervating motor neurons.

Muscular dystrophies (DIS-tró-feez) Inherited muscle-damaging diseases, characterized by degeneration of muscle fibers (cells), which causes progressive atrophy of the skeletal muscle.

Muscularis (MUS-kuh-lar-iss) A muscular layer (coat or tunic) of an organ.

Muscularis mucosae (muh-KÖ-sá) A thin layer of smooth muscle fibers that underlie the lamina propria of the mucosa of the gastrointestinal tract.

Muscular tissue A tissue specialized to produce motion in response to muscle action potentials and by its qualities of contractility, extensibility, elasticity, and excitation; types include skeletal, cardiac, and smooth.

Mutation (mu-TA-shun) Any change in the sequence of bases in a DNA molecule resulting in a permanent alteration in some inheritable trait.

Myasthenia (mi-as-THÉ-né-ah) Weakness and fatigue of skeletal muscles caused by antibodies directed against acetylcholine receptors.

Myelin (MÉ-i-lin) sheath Multilayered lipid and protein covering, formed by Schwann cells and oligodendrocytes, around axons of many peripheral and central nervous system neurons.

Myenteric plexus A network of autonomic axons and postganglionic cell bodies located in the muscularis of the gastrointestinal tract. Also called the plexus of Auerbach (OW-er-bak).

Myocardial infarction (mi-KÖ-deal in-FARK-shun) (MI) Gross necrosis of myocardial tissue due to interrupted blood supply. Also called a heart attack.

Myocardium (mi-KÖ-dre-um) The middle layer of the heart wall, made up of cardiac muscle tissue, lying between the epicardium and the endocardium and constituting the bulk of the heart.

Myofibril (mi-oh-FIR-il) A threadlike structure, extending longitudinally through a muscle fiber (cell) consisting mainly of thick filaments (myosin) and thin filaments (actin, troponin, and tropomyosin).

Myoglobin (mi-oh-GLOB-in) The oxygen-binding, iron-containing protein present in the sarcoplasm of muscle fibers (cells); contributes the red color to muscle.

Myogram (mi-OG-ram) The record or tracing produced by a myograph, an apparatus that measures and records the force of muscular contractions.

Myology (mi-OL-oh-je) The study of muscles.

Myometrium (mi-OM-e-trum) The smooth muscle layer of the uterus.

Myopathy (mi-OP-a-the) Any abnormal condition or disease of muscle tissue.

Myopia (mi-OP-e-a) Defect in vision in which objects can be seen distinctly only when very close to the eyes; nearsightedness.

Myosin (mi-oh-sin) The contractile protein that makes up the thick filaments of muscle fibers.

Myotome (mi-oh-TOM) A group of muscles innervated by the motor neurons of a single spinal segment. In an embryo, the portion of a somite that develops into some skeletal muscles.
Neck  The part of the body connecting the head and the trunk. A constricted portion of an organ, such as the neck of the femur or uterus.

Necrosis (ne-KRO-sis) A pathological type of cell death that results from disease, injury, or lack of blood supply in which many adjacent cells swell, burst, and spill their contents into the interstitial fluid, triggering an inflammatory response.

Neonatal (né-ô-NA-tal) Pertaining to the first four weeks after birth.

Neoplasm (NE-ô-plazm) A new growth that may be benign or malignant.

Nephron (NEF-ron) The functional unit of the kidney.

Nerve A cordlike bundle of neuronal axons and/or dendrites and associated connective tissue coursing together outside the central nervous system.

Nerve fiber  General term for any process (axon or dendrite) projecting from the cell body of a neuron.

Nerve impulse  A wave of depolarization and repolarization that self-propagates along the plasma membrane of a neuron; also called a nerve action potential.

Nervous tissue  Tissue containing neurons that initiate and conduct nerve impulses to coordinate homeostasis, and neuroglia that provide support and nourishment to neurons.

Neuralgia (noo-RÖG-lé-a) Attacks of pain along the entire course or branch of a peripheral sensory nerve.

Neural plate  A thickening of ectoderm, induced by the notochord, that forms early in the third week of development and represents the beginning of the development of the nervous system.

Neural tube defect (NTD) A developmental abnormality in which the neural tube does not close properly. Examples are spina bifida and anencephaly.

Neuritis (noo-RÍ-tis) Inflammation of one or more nerves.

Neurofibril node  See Node of Ranvier.

Neuroglia (noo-RÖG-lé-a) Cells of the nervous system that perform various supportive functions. The neuroglia of the central nervous system are the astrocytes, oligodendrocytes, microglia, and ependymal cells; neuroglia of the peripheral nervous system include Schwann cells and satellite cells. Also called glial (GLE-al) cells.

Neurohypophyseal  (noo’-rö-lí’-pö-FIZ-é-al) bud  An outgrowth of ectoderm located on the floor of the hypophysis that gives rise to the posterior pituitary.

Neurone  The peripheral, nucleated cytoplasmic layer of the Schwann cell. Also called sheath of Schwann (SCHWON).

Neurology (noo-ROL-ô-jé) The study of the normal function and disorders of the nervous system.

Neuromuscular (noo-rö-MUS-ku-lar) junction (NML) A synapse between the axon terminals of a motor neuron and the sarcolemma of a muscle fiber (cell).

Neuron (NOO-rón) A nerve cell, consisting of a cell body, dendrites, and an axon.

Neurosecretory (noo-rö-SÉC-re-tô-ré) cell  A neuron that secretes a hypothalamic releasing hormone or inhibiting hormone into blood capillaries of the hypothalamus; a neuron that secretes oxytocin or antidiuretic hormone into blood capillaries of the posterior pituitary.

Neurotransmitter  One of a variety of molecules within axon terminals that are released into the synaptic cleft in response to a nerve impulse and that change the membrane potential of the postsynaptic neuron.

Neurulation (noor-oo-LÅ-nshun) The process by which the neural plate, neural folds, and neural tube develop.

Neuropil (NOO-trô-fil) A type of white blood cell characterized by granules that stain pale lilac with a combination of acidic and basic dyes.

Nipple  A pigmented, wrinkled projection on the surface of the breast that is the location of the openings of the lactiferous ducts for milk release.

Node of Ranvier (RON-vë-å) A space along a myelinated axon between the individual Schwann cells that form the myelin sheath and the neurolemma. Also called a neurofibril node.

Norepinephrine (nor’é-pë-NÉ-fir-in) (NE) A hormone secreted by the adrenal medulla that produces actions similar to those that result from sympathetic stimulation. Also called noradrenaline (nor-a-DREN-a-lin).

Notochord (NO-tô-cor-d) A flexible rod of mesodermal tissue that lies where the future vertebral column will develop and plays a role in induction.

Nucleic (noo-KLÉ-ic) acid  An organic compound that is a long polymer of nucleotides, with each nucleotide containing a pentose sugar, a phosphate group, and one of four possible nitrogenous bases (adenine, cytosine, guanine, and thymine or uracil).

Nucleolus (noo-KLÉ-ô-lus) Spherical body within a nucleus composed of protein, DNA, and RNA that is the site of the assembly of small and large ribosomal subunits. Plural is nucleoles.

Nucleosome (NOO-klé-ô-söm) Structural subunit of a chromosome consisting of histones and DNA.

Nucleus (NOO-kús) A spherical or oval organelle of a cell that contains the hereditary factors of the cell, called genes. A cluster of unmyleinated nerve cell bodies in the central nervous system. The central part of an atom made up of protons and neutrons.

Nucleus pulposus (pul-PÔ-sus) A soft, pulpy, highly elastic substance in the center of an intervertebral disc; a remnant of the notochord.

Nutrient  A chemical substance in food that provides energy, forms new body components, or assists in various body functions.

O  Obesity (ô-BÉS-i-té) Body weight more than 20% above a desirable standard due to excessive accumulation of fat.

Oblique (ô-BLEK) plane  A plane that passes through the body or an organ at an angle between the transverse plane and either the midsagittal, parasagittal, or frontal plane.

Obstetrics (ôb-STÉT-riks) The specialized branch of medicine that deals with pregnancy, labor, and the period of time immediately after delivery (about 6 weeks).

Olfactory (ôl-FAK-tô-ré) Pertaining to smell.

Olfactory bulb  A mass of gray matter containing cell bodies of neurons that form synapses with neurons of the olfactory (I) nerve, lying inferior to the frontal lobe of the cerebrum on either side of the crista galli of the ethmoid bone.

Olfactory receptor  A bipolar neuron with its cell body lying between supporting cells located in the mucous membrane lining the superior portion of each nasal cavity; transduces odors into neural signals.

Olfactory tract  A bundle of axons that extends from the olfactory bulb posteriorly to olfactory regions of the cerebral cortex.

Oligodendrocyte (OL-i-gö-den-DRÖ-sit) A neuronal cell that supports neurons and produces a myelin sheath around axons of neurons of the central nervous system.

Oliguria (ôl-i-GÜ-ré-a) Daily urinary output usually less than 250 ml.

Olive  A prominent oval mass on each lateral surface of the superior part of the medulla oblongata.

Oncogenes (ON-kö-jenz) Cancer-causing genes; they derive from normal genes, termed protooncogenes, that encode proteins involved in cell growth or cell regulation but have the ability to transform a normal cell into a cancerous cell when they are mutated or inappropriately activated. One example is p53.

Oncology (on-KÖL-ô-jé) The study of tumors.

Oogenesis (ô-gô-NÉ-siz) Formation and development of female gametes (oocytes).

Oophorectomy (ô-of-ô-REK-tô-me) Surgical removal of the ovaries.

Ophthalmic (ôf-THAL-mik) Pertaining to the eye.

Ophthalmology (ôf-thal-MOL-ô-jé)  The study of the structure, function, and diseases of the eye.

Optic (OP-tik) Refers to the eye, vision, or properties of light.

Optic chiasma (ki-AZ-ma) A crossing point of the two branches of the optic (II) nerve, anterior to the pituitary gland. Also called optic chiasm.

Optic disc  A small area of the retina containing openings through which the axons of the ganglion cells emerge as the optic (II) nerve. Also called the blind spot.

Optic tract  A bundle of axons that carry nerve impulses from the retina of the eye between the optic chiasm and the thalamus.
Ora serrata (Ö-ra ser-RÄ-ta) The irregular margin of the retina lying internal and slightly posterior to the junction of the choroid and ciliary body.

Orbit (OR-bit) The bony, pyramidal-shaped cavity of the skull that holds the eyeball.

Organ A structure composed of two or more different kinds of tissues with a specific function and usually recognizable shape.

Organelle (or-gan-EL) A permanent structure within a cell with characteristic morphology that specializes to serve a specific function in cellular activities.

Organism (OR-ga-nizm) A total living form; one individual.

Organogenesis (or-ga-nö-JEN-e-sis) The formation of body organs and systems. By the end of the eighth week of development, all major body systems have begun to develop.

Orifice (OR-i-fis) Any aperture or opening.

Origin (OR-i-jin) The attachment of a muscle tendon to a stationary bone or the end opposite the insertion.

Oropharynx (or’-o-FAR-inks) The intermediate portion of the pharynx, lying posterior to the mouth and extending from the soft palate to the hyoid bone.

Orthopedics (or’-thö-PE-diks) The branch of medicine that deals with the preservation and restoration of the skeletal system, articulations, and associated structures.

Osmoreceptor (oz-more-cep-tor) Receptor in the hypothalamus that is sensitive to changes in blood osmolarity and, in response to high osmolarity (low water concentration), stimulates synthesis of antidiuretic hormone (ADH).

Osmosis (oz-MÖ-sis) The net movement of water molecules through a selectively permeable membrane from an area of higher water concentration to an area of lower water concentration until osmotic equilibrium is reached.

Osseous (OS-é-ous) Bony.

Ossicle (os-si-kul) One of the small bones of the middle ear (malleus, incus, stapes).

Ossification (os-fi-KÁ-shun) Formation of bone. Also called osteogenesis.

Ossification (os-fi-KÁ-shun) center An area in the cartilage model of a future bone where the cartilage cells hypertrophy, secrete enzymes that catalyze their extracellular matrix, and die, and the area they occupied is invaded by osteoblasts that then lay down bone.

Osteoblast (OS-té-ö-blast’) Cell formed from an osteogenic cell that participates in bone formation by secreting some organic components and inorganic salts.

Osteoclast (OS-té-ö-clast’) A large, multinuclear cell that resorbs (destroys) bone matrix.

Osteocyte (OS-té-ö-sit’) A mature bone cell that maintains the daily activities of bone tissue.

Osteogenic (os-té-Ö-jen-i-k) cell Stem cell derived from mesenchyme that has mitotic potential and the ability to differentiate into an osteoblast.

Osteogenic layer The inner layer of the periosteum that contains cells responsible for forming new bone during growth and repair.

Osteology (os-té-OL-ö-jé) The study of bones.

Osteon (OS-té-on) The basic unit of structure in adult compact bone, consisting of a central (haversian) canal with its concentrically arranged lamellae, lacunae, osteocytes, and canaliculi. Also called a haversian (ha-VER-shan) system.

Osteoporosis (os-té-ö-pö-RÖ-sis) Age-related disorder characterized by decreased bone mass and increased susceptibility to fractures, often as a result of decreased levels of estrogens.

Otic (O-tik) Pertaining to the ear.

Otolith (O-tol-ith) A particle of calcium carbonate embedded in the otolithic membrane that functions in maintaining static equilibrium.

Otolithic (o-tol-LITH-ik) membrane Thick, gelatinous, glycoprotein layer located directly over hair cells of the macula in the saccule and utricle of the internal ear.

Otohinolaryngology (o-to-hin-o-LAR-ön-göl-je) The bony, pyramidal-shaped cavity of the skull that holds the eyeball.

P wave The deflection wave of an electrocardiogram that signifies atrial depolarization.

Pacinian corpuscle Oval-shaped pressure receptor located in the dermis or subcutaneous tissue and consisting of concentric layers of a connective tissue wrapped around the dendrites of a sensory neuron. Also called a lamellated corpuscle.

Palate (PAL-aet) The horizontal structure separating the oral and the nasal cavities; the roof of the mouth.

Palpate (PAL-pät) To examine by touch; to feel.

Pancreas (PAN-kre-as) A soft, oblong organ lying along the greater curvature of the stomach and connected by a duct to the duodenum. It is both an exocrine gland (secreting pancreatic juice) and an endocrine gland (secreting insulin, glucagon, somatostatin, and pancreatic polypeptide).

Pancreatic (pa-kré-AT-ik) duct A single large tube that unites with the common bile duct from the liver and gallbladder and drains pancreatic juice into the duodenum at the hepatopancreatic ampulla (ampulla of Vater). Also called the duct of Wirsung.

Pancreatic islet A cluster of endocrine gland cells in the pancreas that secretes insulin, glucagon, somatostatin, and pancreatic polypeptide. Also called an islet of Langerhans (LANG-er-hanz).

Papanicolaou (pa-pa-NI-kö-lö) test A cytological staining test for the detection and diagnosis of pre-malignant and malignant conditions of the female genital tract. Cells scraped from the epithelium of the cervix of the uterus are examined microscopically. Also called a Pap test or Pap smear.

Papilla (pa-PIL-a) A small nipple-shaped projection or elevation.

Paralysis (pa-RAL-a-sis) Loss or impairment of motor function due to a lesion of nervous or muscular origin.

Paranasal sinus (pa-RA-nal-sis) A mucus-lined air cavity in a skull bone that communicates with the nasal cavity. Paranasal sinuses are located in the frontal, maxillary, ethmoid, and sphenoid bones.

Paraplegia (pa-para-PLÉ-jé-a) Paralysis of both lower limbs.

Parasagittal plane (pa-para-SAJ-i-tal) A vertical plane that does not pass through the midline and that divides the body or organs into unequal left and right portions.

Parasympathetic (pa-para-sim-pa-THET-ik) division One of the two subdivisions of the autonomic nervous system, having cell bodies of preganglionic neurons in nuclei in the brain stem and in the lateral gray horn of the sacral portion of the spinal cord; primarily concerned with activities that conserve and restore body energy.

Parathyroid (pa-para-THY-roid) gland One of usually four small endocrine glands embedded in the posterior surfaces of the lateral lobes of the thyroid gland.

Parathyroid hormone (PTH) A hormone secreted by the chief (principal) cells of the parathyroid glands that increases blood calcium level and decreases blood phosphate level.

Parauerebral (pa-para-Ż-RE-thral) gland Gland embedded in the wall of the urethra whose duct opens on either side of the urethral orifice and secretes mucus. Also called Skene’s (SKENZ) gland.

Parenchyma (pa-ڑEN-kì-ma) The functional parts of any organ, as opposed to tissue that forms its stroma or framework.

Parietal (pa-RI-al) Pertaining to or forming the outer wall of a body cavity.

Parietal cell A type of secretory cell in gastric glands that produces hydrochloric acid and intrinsic factor. Also called an oxyntic cell.

Parietal pleura (pLOO-ra) The outer layer of the serous pleural membrane that encloses and
Patent ductus arteriosus  A congenital heart defect in which the ductus arteriosus remains open. As a result, aortic blood flows into the lower-pressure pulmonary trunk, increasing pulmonary blood flow and decreasing oxygen saturation of the pulmonary vessels, which results in decreased pulmonary blood flow and increased aortic blood flow.

Parotid  One of the paired salivary glands located inferior and anterior to the ears and connected to the oral cavity via a duct (Stensen's duct). These glands produce saliva that contains amylase and other digestive enzymes.

Patent ductus arteriosus  A congenital heart defect in which the ductus arteriosus remains open. As a result, aortic blood flows into the lower-pressure pulmonary trunk, increasing pulmonary blood flow and decreasing oxygen saturation of the pulmonary vessels, which results in decreased pulmonary blood flow and increased aortic blood flow.

Pelvic  (PEL-vik)  The part of the pelvic cavity that contains the urinary bladder, sigmoid colon, rectum, and internal female and male reproductive structures.

Pelvic splanchnic  (PEL-vik SPLA-NK-ik)  Nerves Consist of preganglionic parasympathetic axons from the levels of S2, S3, and S4 that supply the urinary bladder, reproductive organs, and the descending and sigmoid colon and rectum.

Pelvis  The basinlike structure formed by the two hip bones, the sacrum, and the coccyx. The expanded, proximal portion of the ureter, lying within the kidney and into which the major calyces open.

Penis  (PEE-nis)  The organ of urination and copulation in males; used to deposit semen into the female vagina.

Pepsin  Protein-digesting enzyme secreted by chief cells of the stomach in the inactive form pepsinogen, which is converted to active pepsin by hydrochloric acid.

Percussion  The act of striking (percussing) an underlying part of the body with short, sharp taps as an aid in diagnosing the part by the quality of the sound produced.

Perforating canal  A minute passageway by means of which blood vessels and nerves from the periosteum penetrate into compact bone. Also called Volkmann's (FOL-k-mans) canal.

Pericardial cavity  Small potential space between the visceral and parietal layers of the serous pericardium that contains pericardial fluid.

Pericardium  (per-i-KAR-de-al)  The pericardial sac is a double-walled membranous cavity around the heart that is lined by a serous pericardium and a fibrous pericardium. The pericardium is formed by the pericardial sac and contains the heart, great vessels, and mediastinal structures.

Perimetrium  (per-i-ME-tre-al)  The serosa of the uterus.

Perineum  (per-i-NEE-um)  The pelvic floor; the space between the anus and the scrotum in the male and between the anus and the vulva in the female.

Perineum  (per-i-NOO-ri-al)  Connective tissue wrapping around fascicles in a nerve.

Peripheral nervous system (PNS)  The part of the nervous system that includes all the nerves outside of the central nervous system. It consists of the sensory nerves and the motor nerves, which carry information from the body to the brain and from the brain to the body.

Peripheral ligament  The periosteum lining the alveoli (sockets) for the teeth in the alveolar processes of the mandible and maxilla.

Peristalsis  (per-i-STAL-sis)  Successive muscular contractions along the wall of a hollow muscular structure.

Peritonitis  (per-i-TOH-ni-tis)  Inflammation of the peritonaeum.

Perineum  (per-i-NEE-um)  The pelvic floor; the space between the anus and the scrotum in the male and between the anus and the vulva in the female.

Peritoneum  (per-i-TOE-num)  The serosa of the peritoneal cavity and peritoneal membranes.

Peritoneum  (per-i-NOO-ri-al)  Connective tissue wrapping around fascicles in a nerve.

Peritonitis  (per-i-TOH-ni-tis)  Inflammation of the peritoneum.

Peritrophic membrane  A thin gel-like membrane that surrounds the food bolus in the small intestine and protects the epithelial lining from the digestive enzymes of the gut.

Peritrichous  (per-i-TRICK-ous)  Having many flagella.

Peyer's patches  See Aggregated lymphatic follicles.

Phagocytosis  (fag-oh-si-TOS-i-sis)  The process by which phagocytes ingest and destroy microbes, cell debris, and other foreign matter.

Phalanges  (FA-lanz)  The bone of a finger or toe. Plural is phalanges (fa-LAN-jees).

Pharmacology  (far-ma-KOL-eh-ji)  The science of the effects and uses of drugs in the treatment of disease.

Pharynx  (far-EENK/)  The throat; a tube that starts at the internal nares and runs posteriorly down the neck, where it opens into the esophagus and pharynx. Also called the pharynx.

Phenotype  (FE-noh-tip)  The observable expression of genotype; physical characteristics of an organism determined by genetic makeup and influenced by interaction between genes and internal and external environmental factors.

Phlebitis  (flew-BI-tis)  Inflammation of a vein, usually in a lower limb.

Photocytosis  The receptor that detects light shining on the retina of the eye.

Photoreceptor  A photosensitive cell that absorbs light and undergoes structural changes that lead to the development of a receptor potential. An example is rhodopsin. Also called visual pigment.

Physiology  (fiz-eh-OL-eh-ji)  Science that deals with the functions of an organism or its parts.

Pia mater  (PI-a MA-tur)  The innermost of the three meninges (coverings) of the brain and spinal cord.

Pineal gland  (PINE-ahl)  A cone-shaped gland located in the roof of the third ventricle that secretes melatonin. Also called the epiphysis cerebri (E-pi-FI-sis se-RE-bré).

Pinealocyte  (PI-nahl-ahl-EYE)  Secretory cell of the pineal gland that releases melatonin.

Pinna  (PIN-na)  The projecting part of the external ear composed of elastic cartilage and covered by skin and shaped like the flared end of a trumpet. Also called the auricle (OR-i-kul).

Pituitary body  (PI-too-i-tur-uh)  Supporting cell of the posterior pituitary.

Pituitary gland  (PI-too-i-tur-uh)  A small endocrine gland occupying the hypophyseal fossa of the sphenoid bone and attached to the hypothalamus by the infundibulum. Also called the hypophysis (HI-po-FI-sis).

Pivot joint  A synovial joint in which a rounded, pointed, or conical surface of one bone articulates with a ring formed partly by another bone and partly by a ligament, as in the joint between the atlas and axis of the cervical spine. Also called a trochoidean joint.

Plantar flexion  (PLAN-tur FLIK-shun)  Bending the foot in the direction of the plantar surface (sole).

Plaque  (PLA-k)  A layer of dense proteins on the inside of a plasma membrane in adherens junctions and desmosomes. A mass of bacterial cells, dextran (polysaccharide), and other debris that
adheres to teeth (dental plaque). See also Atherosclerotic plaque.

Plasma (PŁAZ-ma) The extracellular fluid found in blood vessels; blood minus the formed elements.

Plasma cell Cell that develops from a B cell (lymphocyte) and produces antibodies.

Plasma (cell) membrane Outer, limiting membrane that separates the cell’s internal parts from extra-cellular fluid or the external environment.

Platelet (PLÁT-let) A fragment of cytoplasm enclosed in a cell membrane and lacking a nucleus; found in the circulating blood, plays a role in hemostasis. Also called a thrombocyte (THROM-bó-sit).

Platelet plug Aggregation of platelets (thromboocytes) at a site where a blood vessel is damaged that helps stop or slow blood loss.

Pleura (PŁOO-ra) The serous membrane that covers the lungs and lines the walls of the chest and the diaphragm.

Pleural cavity Small potential space between the visceral and parietal pleurae.

Plexus (PLEK-sus) A network of nerves, veins, or lymphatic vessels.

Plexus of Auerbach See Myenteric plexus.

Plexus of Meissner See Submucosal plexus.

Pluripotent stem cell Immature stem cell in red bone marrow that gives rise to precursors of all the different mature blood cells.

Pneumotaxic (nóo-mó-TAK-sik) area A part of the respiratory center in the pons that continually sends inhibitory nerve impulses to the inspiratory area, limiting inhalation and facilitating exhalation.

Polychthemia (pol-é-sí-THE-mé-a) Disorder characterized by an above-normal hematocrit (above 55%) in which hypertension, thrombosis, and hemorrhage can occur.

Polyunsaturated fat A fatty acid that contains more than one double covalent bond between its carbon atoms; abundant in triglycerides of corn oil, safflower oil, and cottonseed oil.

Pons (PONZ) The part of the brain stem that forms a “bridge” between the medulla oblongata and the midbrain, anterior to the cerebellum.

Portal system The circulation of blood from one capillary network into another through a vein.

Postcentral gyrus Gyrus of cerebral cortex located immediately posterior to the central sulcus; contains the primary somatosensory area.

Posterior (pos-TÉR-é-or) Near to or at the back of the body. Equivalent to dorsal in bipeds.

Posterior column–medial lemniscus pathways Sensory pathways that carry information related to proprioception, fine touch, two-point discrimination, pressure, and vibration. First-order neurons project from the spinal cord to the ipsilateral medulla in the posterior columns (gracile fasciculus and cuneate fasciculus). Second-order neurons project from the medulla to the contralateral thalamus in the medial lemniscus. Third-order neurons project from the thalamus to the somatosensory cortex (postcentral gyrus) on the same side.

Posterior pituitary Posterior lobe of the pituitary gland. Also called the neurohypophysis (noo-ro-hí-POF-i-sis).

Posterior root The structure composed of sensory axons lying between a spinal nerve and the dorsal-solateral aspect of the spinal cord. Also called the dorsal (sensory) root.

Posterior root ganglion (GAN-Glé-on) A group of cell bodies of sensory neurons and their supporting cells located along the posterior root of a spinal nerve. Also called a dorsal (sensory) root ganglion.

Postganglionic neuron (póst-gán-glé-on-ik) neuron The second axon carried by a preganglionic neuron as it travels from the spinal cord to its target organ. The postganglionic neuron has a cell body located in a ganglion associated with a particular autonomic nerve pathway. It has axons lying between a spinal nerve and the dorsal root ganglion.

Posterior lobe of the pituitary A region of the cerebrovascular system that controls specific muscles or groups of muscles.

Posterior somatosensory area A region of the cerebral cortex posterior to the central sulcus in the postcentral gyrus of the parietal lobe of the cerebral cortex that controls specific muscles or groups of muscles.

Prime mover The muscle directly responsible for producing a desired motion. Also called an agonist (AG-ón-ist).

Primitive gut Embryonic structure formed from the dorsal part of the yolk sac that gives rise to most of the gastrointestinal tract.

Primordial (pré-MOHR-de-al) Existing first; especially primordial egg cells in the ovary.

Principal cell Cell type in the distal convoluted tubules and collecting ducts of the kidneys that is stimulated by aldosterone and antidiuretic hormone.

Proctology (prok-TOOL-é-jé) The branch of medicine concerned with the rectum and its disorders.

Progeny (pré-JEN-es) Offspring or descendants.

Progesterone (pré-jes-tes-ron) A female sex hormone produced by the ovaries that helps prepare the endometrium of the uterus for implantation of a fertilized ovum and the mammary glands for milk secretion.

Prognosis (pro-JEN-o-sis) A forecast of the probable results of a disorder; the outlook for recovery.

Prolactin (pré-LAHT-in) A hormone secreted by the anterior pituitary that initiates and maintains milk secretion by the mammary glands.

Prolapse (pré-láps) A dropping or falling down of an organ, especially the uterus or rectum.

Proliferation (pré-lif-er-á-shun) Rapid and repeated reproduction of new parts, especially cells.

Pronation (pré-ná-shun) A movement of the forearm in which the palm is turned posteriorly.

Prophase (pré-fáz) The first stage of mitosis during which chromatid pairs are formed and aggregate around the metaphase plate of the cell.

Proprioeception (pré-pré-ó-SEP-shun) The perception of the position of body parts, especially the limbs, independently of vision; this sense is possible due to nerve impulses generated by proprioceptors.

Proprioeceptor (pré-pré-ó-SEP-tor) A receptor located in muscles, tendons, joints, or the internal ear (muscle spindles, tendon organs, joint kinesthetic receptors, and hair cells of the vestibular apparatus) that provides information about body position and movements.

Prostaglandin (pré-ság-land-in) (PG) A membrane-associated lipid; released in small quantities and acts as a local hormone.

Prostate (pros-tá-té) A doughnut-shaped gland inferior to the urinary bladder that surrounds the superior portion of the male urethra and secretes a slightly acidic solution that contributes to sperm motility and viability.

Proteasome (pré-té-a-sóm) Tiny cellular organelle in cytosol and nucleus containing proteases that destroy unneeded, damaged, or faulty proteins.

Protein An organic compound consisting of carbon, hydrogen, oxygen, nitrogen, and sometimes sulfur and phosphorus; synthesized on ribosomes and made up of amino acids linked by peptide bonds.
G22 GLOSSARY

Prothrombin (prō-THROM-bin) An inactive blood-clotting factor synthesized by the liver, released into the blood, and converted to active thrombin in the process of blood clotting by the activated enzyme prothrombinase.

Proto-oncogene (prō′-ō-ON-kō-jēn) Gene responsible for some aspect of normal growth and development; it may transform into an oncogene, a gene capable of causing cancer.

Protrusion (prō-TRAK-shun) The movement of the mandible or shoulder girdle forward on a plane parallel with the ground.

Proximal (prōK-sī-mal) Nearest the attachment of a limb to the trunk; nearer to the point of origin or attachment.

Pseudopods (SOO-do¯-pods) Temporary protrusions of the leading edge of a migrating cell; cellular projections that surround a particle undergoing phagocytosis.

Pterygopalatine ganglion (ter′i-gō-PAL-a-tīn GAN-glē-on) A cluster of cell bodies of parasympathetic post-ganglionic neurons ending at the lacrimal and nasal glands.

Ptosis (TO¯-sis) Drooping, as of the eyelid or the kidney.

Puberty (PUB-er-tē) The time of life during which the secondary sex characteristics begin to appear and the capability for sexual reproduction is possible; usually occurs between the ages of 10 and 17.

Pubic symphysis (PE) A slightly movable cartilaginous joint between the anterior surfaces of the hip bones.

Puoperium (pū′-er-PER-ē-um) The period immediately after childbirth, usually 4–6 weeks.

Pulmonary (PUL-mo-ne′-ē) Concerning or affected by the lungs.

Pulmonary circulation The flow of deoxygenated blood from the right ventricle to the lungs and the return of oxygenated blood from the lungs to the left atrium.

Pulmonary edema An abnormal accumulation of interstitial fluid in the tissue spaces and alveoli of the lungs due to increased pulmonary capillary permeability or increased pulmonary capillary pressure.

Pulmonary embolism (EM-bō-li-zm) (PE) The presence of a blood clot or a foreign substance in a pulmonary arterial blood vessel that obstructs circulation to lung tissue.

Pulmonary ventilation The inflow (inhalation) and outflow (exhalation) of air between the atmosphere and the lungs. Also called breathing.

Pulp cavity The hole in the center of the iris, the area through which light enters the posterior cavity of the eyeball.

Purkinje (pur-KIN-jē) fiber Muscle fiber (cell) in the ventricular tissue of the heart specialized for conducting an action potential to the myocardium; part of the conduction system of the heart.

Pus The liquid product of inflammation containing leukocytes or their remains and debris of dead cells.

Pyloric (pi-LOR-ik) sphincter A thickened ring of smooth muscle muscle through which the pylorus of the stomach communicates with the duodenum. Also called the pyloric valve.

Pyorrhea (pi-ō-RE-a) A discharge or flow of pus, especially in the alveoli (sockets) and the tissues of the gums.

Pyramidal (PIR-a-mid) A pointed or cone-shaped structure. One of two roughly triangular structures on the anterior aspect of the medulla oblon-gata composed of the larger motor tracts that run from the cerebral cortex to the spinal cord. A triangular structure in the renal medullia.

Pyramidal (pi-RAM-i-dal) tracts (pathways). See Direct motor pathways.

Q QRS wave The deflection waves of an electrocardiogram that represent onset of ventricular depolarization.

Quadrant (KWOD-rant) One of four parts.

Quadriplegia (kwōrd′-ri-PLE-jē-a) Paralysis of four limbs: two upper and two lower.

R Radiographic (rā′-dē-o-GRAF-ic) anatomy Diagnostic branch of anatomy that includes the use of x rays.

Rami communicantes (RĀ′-mē-kō-mō-ni-KAN-tēz) Branches of a spinal nerve. Singular is ramus communicans (RĀ′-mus-kō-MU′-ni-kans).

Receptor A specialized cell or a distal portion of a neuron that responds to a specific sensory modality, such as touch, pressure, cold, light, or sound, and converts it to an electrical signal (generator or receptor potential). A specific molecule or cluster of molecules that recognizes and binds a particular ligand.

Receptor-mediated endocytosis A highly selective process whereby cells take up specific ligands, which usually are large molecules or particles, by enveloping them within a sac of plasma membrane. Ligands are eventually broken down by enzymes in lysosomes.

Recombinant DNA Synthetic DNA, formed by joining a fragment of DNA from one source to a portion of DNA from another.

Rectangular pouch A pocket formed by the parietal peritoneum as it moves posteriorly from the surface of the uterus and is reflected onto the rectum; the most inferior point in the pelvic cavity. Also called the pouch or cul de sac of Douglas.

Rectum (rek′-tum) The last segment (8 in.) of the gastrointestinal tract, from the sigmoid colon to the anus.

Recumbent (re-KUM-bent) Lying down.

Red bone marrow A highly vascularized connective tissue located in microscopic spaces between trabeculae of spongy bone tissue.

Red nucleus A cluster of cell bodies in the midbrain, occupying a large part of the tectum from which axons extend into the rubroreticular and rubrospinal tracts.

Red pulp That portion of the spleen that consists of venous sinuses filled with blood and thin plates of splenic tissue called splenic (Billroth’s) cords.

Referred pain Pain that is felt at a site remote from the place of origin.

Reflex Fast response to a change (stimulus) in the internal or external environment that attempts to restore homeostasis.

Reflex arc The most basic conduction pathway through the nervous system, connecting a receptor and an effector and consisting of a receptor, a sensory neuron, an integrating center in the central nervous system, a motor neuron, and an effector.

Regional anatomy The division of anatomy dealing with specific regions of the body, such as the head, neck, chest, or abdomen.

Regurgitation (RE-gur′-ji-TA-shun) Return of solids or fluids to the mouth from the stomach; backward flow of blood through incompletely closed heart valves.

Relaxin (RLX) A female hormone produced by the ovaries and placenta that increases flexibility of the pubic symphysis and helps dilate the uterine cervix to ease delivery of a baby.

Releasing hormone Hormone secreted by the hypothalamus that can stimulate secretion of hormones of the anterior pituitary.

Remodeling Replacement of old bone by new bone tissue.

Renal (RE-nal) Pertaining to the kidneys.

Renal corpuscle (KOR-pus-l) A glomerular (Bowman’s) capsule and its enclosed glomerulus.

Renal pelvis A cavity in the center of the kidney formed by the expanded, proximal portion of the ureter, lying within the kidney, and into which the major calyces open.

Renal pyramid A triangular structure in the renal medulla containing the straight segments of renal tubules and the vasa recta.

Reproduction (rē-prō-DUK-shun) The formation of new cells for growth, repair, or replacement; the production of a new individual.

Reproductive cell division Type of cell division in which gametes (sperm and oocytes) are produced; consists of meiosis and cytokinesis.

Respiration (res-pi-RA-shun) Overall exchange of gases between the atmosphere, blood, and body cells consisting of pulmonary ventilation, external respiration, and internal respiration.

Respiratory center Neurons in the pons and medulla oblongata of the brain stem that regulate the rate and depth of pulmonary ventilation.

Retention (rē-TEN-shun) A failure to void urine due to obstruction, nervous contraction of the urethra, or absence of sensation of desire to urinate.

Rete (RĒ-tē) testis The network of ducts in the testes.

Reticular (re-TIK-ō-lar) activating system (RAS) A portion of the reticular formation that has many ascending connections with the cerebral cortex; when this area of the brain stem is active, nerve impulses pass to the thalamus and widespread areas of the cerebral cortex, resulting in generalized alertness or arousal from sleep.
Reticular formation A network of small groups of neuronal cell bodies scattered among bundles of axons (mixed gray and white matter) beginning in the medulla oblongata and extending superiorly through the central part of the brain stem.

Reticuloyte (re-TIK-ū-tō-sīt) An immature red blood cell.

Reticulum (re-TIK-ū-lum) A network.

Retina (RET-i-na) The deep coat of the posterior portion of the eyeball consisting of nervous tissue (where the process of vision begins) and a pigmented layer of epithelial cells that contact the choroid.

Retinaculum (ret-i-NAK-ū-lum) A thickening of fascia that holds structures in place, for example, the superior and inferior retinaculum of the ankle.

Retraction (re-TRAK-shun) The movement of a protracted part of the body posteriorly on a plane parallel to the ground, as in pulling the lower jaw back in line with the upper jaw.

Retropertoneal (re-tōr-per-i-to-NĒ-al) External to the peritoneal lining of the abdominal cavity.

Rh factor An inherited antigen on the surface of red blood cells in Rh- individuals; not present in Rh+ individuals.

Rhinology (rī-NOL-ō-jē) The study of the nose and its disorders.

Ribonucleic (rī-bō-nū-kō-NEL-ē-ik) acid (RNA) A single-stranded nucleic acid made up of nucleotides, each consisting of a nitrogenous base (adenine, cytosine, guanine, or uracil), ribose, and a phosphorus group; three types are messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA), each of which has a specific role during protein synthesis.

Ribosome (RI-bō-sōm) A cellular structure in the cytoplasm of cells, composed of a small subunit and a large subunit that contain ribosomal RNA and ribosomal proteins; the site of protein synthesis.

Right lymphatic (lim-FAT-ik) duct A vessel of the lymphatic system that drains lymph from the upper right side of the body and empties it into the right subclavian vein.

Rigidity (RI-jī-di-tē) Hypertonia characterized by increased muscle tone, but reflexes are not affected.

Rigor mortis State of partial contraction of muscles after death due to lack of ATP; myosin heads (crossbridges) remain attached to actin, thus preventing relaxation.

Rod One of two types of photoreceptor in the retina of the eye; specialized for vision in dim light.

Root canal A narrow extension of the pulp cavity lying within the root of a tooth.

Root of penis Attached portion of penis that consists of the bulb and crura.

Rotation (rō-TĀ-shun) Moving a bone around its own axis, with no other movement.

Round ligament (LIG-a-ment) A band of fibrous connective tissue enclosed between the folds of the broad ligament of the uterus, emerging from the uterus just inferior to the uterine tube, extending laterally along the pelvic wall and through the deep inguinal ring to end in the labia majora.

Round window A small opening between the middle and internal ear, directly inferior to the oval window, covered by the secondary tympanic membrane.

Rufini corpuscle A sensory receptor embedded deeply in the dermis and deeper tissues that detects the stretching of the skin.

Rugae (ROO-gé) Large folds in the mucosa of an empty hollow organ, such as the stomach and vagina.

S

Saccule (SAK-ūl) The inferior and smaller of the two chambers in the membranous labyrinth inside the vestibule of the internal ear containing a receptor organ for static equilibrium.

Sacral plexus (SA-rāl PLEK-sus) A network formed by the ventral branches of spinal nerves L4 through S3.

Sacral promontory (PROM-on-to-rē) The superior surface of the body of the first sacral vertebra that projects anteriorly into the pelvic cavity; a line from the sacral promontory to the superior border of the pubic symphysis divides the abdominal and pelvic cavities.

Saddle joint A synovial joint in which the articular surface of one bone is saddle-shaped and the articular surface of the other bone is shaped like the legs of the rider sitting in the saddle, as in the joint between the trapezium and the metacarpal of the thumb.

Sagittal (SA(I-t)al) plane A plane that divides the body or organs into left and right portions. Such a plane may be midsagittal (median), in which the divisions are equal, or parasagittal, in which the divisions are unequal.

Saliva (sa-LĪ-va) A clear, alkaline, somewhat viscous secretion produced mostly by the three pairs of salivary glands; contains various salts, mucin, lysozyme, salivary amylase, and lingual lipase (produced by glands in the tongue).

Salivary amylase (SA-LI-AM-i-lās) An enzyme in saliva that initiates the chemical breakdown of starch.

Salivary gland One of three pairs of glands that lie external to the mouth and pour their secretory product (saliva) into ducts that empty into the oral cavity (the parotid, submandibular, and sublingual glands).

Sarclemma (sārk-LĒ-ma) The cell membrane of a muscle fiber (cell), especially of a skeletal muscle fiber.

Sarcomere (SAR-kō-mēr) A contractile unit in a striated muscle fiber (cell) extending from one Z disc to the next Z disc.

Sarcoplasm (SAR-kō-pláz-m) The cytoplasm of a muscle fiber (cell).

Sarcoplasmic reticulum (sārk-o-plaz-mik ret-IK-ō-lum) SR A network of sacules and tubes surrounding myofibrils of a muscle fiber (cell), comparable to endoplasmic reticulum; functions to reabsorb calcium ions during relaxation and to release them to cause contraction.

Satellite cell (SAT-ī-līt) Flat neuroglial cells that surround cell bodies of peripheral nervous system ganglia to provide structural support and regulate the exchange of material between a neuronal cell body and interstitial fluid.

Saturated fat A fatty acid that contains only single bonds (no double bonds) between its carbon atoms; all carbon atoms are bonded to the maximum number of hydrogen atoms; prevalent in triglycerides of animal products such as meat, milk, milk products, and eggs.

Scala tympani (SKA-lā TIM-pān-E) The inferior spiral-shaped channel of the bony cochlea, filled with perilymph.

Scala vestibuli (ves-TĪB-ī-tē) The superior spiral-shaped channel of the bony cochlea, filled with perilymph.

Schwann (SCHWON) cell A neuroglial cell of the peripheral nervous system that forms the myelin sheath and neurolemma around a nerve axon by wrapping around the axon in a jelly-roll fashion.

Sciatrica (sī-AT-i-ka) Inflammation and pain along the sciatic nerve; felt along the posterior aspect of the thigh extending down the inside of the leg.

Sclera (SKLĒ-rah) The white coat of fibrous tissue that forms the superficial protective covering over the eyeball except in the most anterior portion; the posterior portion of the fibrous tunic.

Scleral venous sinus A circular venous sinus located at the junction of the sclera and the cornea through which aqueous humor drains from the anterior chamber of the eyeball into the blood. Also called the canal of Schlemm (SHLEM).

Sclerosis (skle-RO-sis) A hardening with loss of elasticity of tissues.

Scotolosis (skō-tō-LO-sis) An abnormal lateral curvature from the normal vertical line of the backbone.

Sclerotum (SKRĒ-tōm) A skin-covered pouch that contains the testes and their accessory structures.

Sebaceous (se-BĀ-shūs) gland An exocrine gland in the dermis of the skin, almost always associated with a hair follicle, that secretes sebum. Also called an oil gland.

Sebum (SE-būm) Secretion of sebaceous (oil) glands.

Secondary sex characteristic A characteristic of the male or female body that develops at puberty under the influence of sex hormones but is not directly involved in sexual reproduction; examples are distribution of body hair, voice pitch, body shape, and muscle development.

Secrecion (se-KRE-shun) Production and release from a cell or a gland of a physiologically active substance.

Selective permeability (per-SE-mēr-a-BIL-ī-tē) The property of a membrane by which it permits the passage of certain substances but restricts the passage of others.

Semien (SE-men) A fluid discharged at ejaculation by a male that consists of a mixture of sperm and the secretions of the seminiferous tubules, seminal vesicles, prostate, and bulbourethral (Cowper’s) glands.

Semicircular canals Three bony channels (anterior, posterior, lateral), filled with perilymph, in which lie the membranous semicircular canals filled with endolymph. They contain receptors for equilibrium.
G24 GLOSSARY

Semicircular ducts The membranous semicircular canals filled with endolymph and floating in the perilymph of the bony semicircular canals; they contain cisternae that are concerned with dynamic equilibrium.

Semilunar (sem’-ë-LOO-nar) valve A valve between the aorta or the pulmonary trunk and a ventricle of the heart.

Seminal vesicle (SEM-i-nal VES-i-kul) One of a pair of convoluted, poulish structures, lying posterior and inferior to the urinary bladder and anterior to the rectum, that secrete a component of semen into the ejaculatory ducts. Also termed seminal gland.

Seminiferous tubule (semi-nifer-us TOO-bul) A tightly coiled duct, located in the testis, where sperm are produced.

Sensation A state of awareness of external or internal conditions of the body.

Sensory area A region of the cerebral cortex concerned with the interpretation of sensory impulses.

Sensory neurons (NOO-ronz) Neurons that carry sensory information from cranial and spinal nerves into the brain and spinal cord or from a lower to a higher level in the spinal cord and brain. Also called afferent neurons.

Septal defect An opening in the atrial septum (atrial septal defect) because the foramen ovale fails to close, or the ventricular septum (ventricular septal defect) due to incomplete development of the ventricular septum.

Septum (SEP-tum) A wall dividing two cavities.

Serosa (sé-RO-sa) A supporting cell in the seminiferous tubules that secretes fluid for supplying nutrients to sperm and the hormone inhibin, removes excess cytoplasm from spermatogenic cells, and mediates the effects of FSH and testosterone on spermatogenesis. Also called a sustentacular (sus’-ten-TAK-lar) cell.

Serum Blood plasma minus its clotting proteins.

Sesamoid (SES-a-moid) bones Small bones usually found in tendons.

Sex chromosomes The twenty-third pair of chromosomes, designated X and Y, which determine the genetic sex of an individual; in males, the pair is XY; in females, XX.

Sexual intercourse The insertion of the erect penis of a male into the vagina of a female. Also called coitus (KO-i-tus).

Sheath of Schwann See Neurolemma.

Shock Failure of the cardiovascular system to deliver adequate amounts of oxygen and nutrients to meet the metabolic needs of the body due to inadequate cardiac output. It is characterized by hypotension; clammy, cool, and pale skin; sweating; reduced urine formation; altered mental state; acidosis; tachycardia; weak, rapid pulse; and thirst. Types include hypovolemic, cardiogenic, vascular, and obstructive.

Shoulder joint A synovial joint where the humerus articulates with the scapula.

Sigmoid colon (SIG-moyd KO-lon) The S-shaped portion of the large intestine that begins at the level of the left iliac crest, projects medially, and terminates at the rectum at about the level of the third sacral vertebra.

Sign Any objective evidence of disease that can be observed or measured, such as a lesion, swelling, or fever.

Sinoatrial (si-noh-AT-er-uhl) (SA) node A small mass of cardiac muscle fibers (cells) located in the right atrium inferior to the opening of the superior vena cava that spontaneously depolarizes and generates a cardiac action potential about 100 times per minute. Also called the natural pacemaker.

Sinus (SI-nus) A hollow in a bone (paranasal sinus) or other tissue; a channel for blood (vascular sinus); any cavity having a narrow opening.

Sinusoid (SI-nus-oid) A large, thin-walled, and leaky type of capillary, having large intercellular clefts that may allow proteins and blood cells to pass from a tissue into the bloodstream; present in the liver, spleen, anterior pituitary, parathyroid glands, and red bone marrow.

Skeletal muscle An organ specialized for contraction, composed of striated muscle fibers (cells), supported by connective tissue, attached to a bone by a tendon or an aponeurosis, and stimulated by somatic motor neurons.

Skene’s gland See Paraurethral gland.

Skin The external covering of the body that consists of a superficial, thinner epidermis (epithelial tissue) and a deep, thicker dermis (connective tissue) that is anchored to the subcutaneous layer.

Skull The skeleton of the head consisting of the cranial and facial bones.

Sleep A state of partial unconsciousness from which a person can be aroused; associated with a low level of activity in the reticular activating system.

Small intestine A long tube of the gastrointestinal tract that begins at the pyloric sphincter of the stomach, coils through the central and inferior part of the abdominal cavity, and ends at the large intestine; divided into three segments: duodenum, jejunum, and ileum.

Smooth muscle A tissue specialized for contraction, composed of smooth muscle fibers (cells), located in the walls of hollow internal organs, and innervated by autonomic motor neurons.

Sodium-potassium ATPase An active transport pump located in the plasma membrane that transports sodium ions out of the cell and potassium ions into the cell at the expense of cellular ATP. It functions to keep the ionic concentrations of these ions at physiological levels. Also called the sodium-potassium pump.

Soft palate (PAL-at) The posterior portion of the roof of the mouth, extending from the palatine bones to the uvula. It is a muscular partition lined with mucous membrane.

Somatic nervous system (SNS) The portion of the peripheral nervous system consisting of somatic sensory (afferent) neurons and somatic motor (efferent) neurons.

Somite (SO-mite) Block of mesodermal cells in a developing embryo that is distinguished into a myotome (which forms most of the skeletal muscles), dermatome (which forms connective tissues), and sclerotome (which forms the vertebrae).

Spasm (SPA-zem) A sudden, involuntary contraction of large groups of muscles.

Stapility (spas-TIS-i-ty) Hypertonia characterized by increased muscle tone, increased tendon reflexes, and pathological reflexes (Babinski sign).

Spermatic (sper-MAT-ik) cord A supporting structure of the male reproductive system, extending from a testis to the deep inguinal ring, that includes the ductus (vas) deferens, arteries, veins, lymphatic vessels, nerves, cremaster muscle, and connective tissue.

Spermatogenesis (sper’-ma-to-JEN-e-sis) The formation and development of sperm in the seminiferous tubules of the testes.

Sperm cell A mature male gamete. Also termed spermatozooon (sper’-ma-to-ZO-on).

Spermiogenesis (sperm-i-jen-e-sis) The maturation of spermatids into sperm.

Sphincter (SFINGK-ter) A circular muscle that constitutes an opening.

Sphincter of Oddi See Sphincter of the hepatopancreatic ampulla.

Sphincter of the hepatopancreatic ampulla A circular muscle at the opening of the common bile and main pancreatic ducts in the duodenum. Also called the sphincter of Oddi (OD-i).

Spinal (SPI-nal) cord A mass of nerve tissue located in the vertebral canal from which 31 pairs of spinal nerves originate.

Spinal nerve One of the 31 pairs of nerves that originate on the spinal cord from posterior and anterior roots.

Spinal shock A period from several days to several weeks following transection of the spinal cord that is characterized by the abolition of all reflex activity.

Spinothalamic (spi-no-thal-AM-ik) tract Sensory (ascending) tract that conveys information up the spinal cord to the thalamus for sensations of pain, temperature, itch, and tickle.

Spinous (SPI-nus) process A sharp or thornlike process or projection. Also called a spine. A sharp ridge running diagonally across the posterior surface of the scapula.

Spiral organ The organ of hearing, consisting of supporting cells and hair cells that rest on the basilar membrane and extend into the endolymph of the cochlear duct. Also called the organ of Corti (KOR-ti).

Splanchnic (SPLANK-nik) Pertaining to the viscera.

Spleen (SPLE-n) Large mass of lymphatic tissue between the fundus of the stomach and the diaphragm that functions in formation of blood cells during early fetal development, phagocytosis of ruptured blood cells, and proliferation of B cells during immune responses.
Spongy (cancellous) bone tissue: Bone tissue that consists of an irregular lattice work of thin plates of bone called trabeculae; spaces between trabeculae of some bones are filled with red bone marrow; found inside short, flat, and irregular bones and in the epiphyses (ends) of long bones.

Sprain: Forcible wrenching or twisting of a joint with partial rupture or other injury to its attachments without dislocation.

Squamous (SKWÁ-mus): Flat or scalelike.

Starvation: The loss of energy stores in the form of glycogen, triglycerides, and proteins due to inadequate intake of nutrients or inability to digest, absorb, or metabolize ingested nutrients.

Static equilibrium: The maintenance of posture in response to changes in the orientation of the body, mainly the head, relative to the ground.

Stellate reticuloendothelial (STEL-e-tik-re-TIK-o-en-dó-thè-lê) cell: Phagocytic cell bordering a sinusoid of the liver. Also called a Kupffer (KOOP-fer) cell.

Stem cell: An unspecialized cell that has the ability to divide for indefinite periods and give rise to a specialized cell.

Stenosis (sten-Ö-sis): An abnormal narrowing or constriction of a duct or opening.

Sterocilia (ste-ré-O-sil-e-a): Groups of extremely long, slender, nonmotile microvilli projecting from epithelial cells lining the epididymis.

Sterile (STE-nil): Free from any living microorganisms. Unable to conceive or produce offspring.

Sterilization (ster-i-il-ZA-shun): Elimination of all living microorganisms. Any procedure that renders an individual incapable of reproduction (for example, castration, vasectomy, hysterectomy, or oophorectomy).

Stimulus: Any stress that changes a controlled condition; any change in the internal or external environment that excites a sensory receptor, a neuron, or a muscle fiber.

Stomach: The J-shaped enlargement of the gastrointestinal tract directly inferior to the diaphragm in the epigastric, umbilical, and left hypochondriac regions of the abdomen, between the esophagus and the transverse colon.

Straight tube (TÚ-bú): A duct in a testis leading from a convoluted seminiferous tubule to the rete testis.

Stratum (STRÁ-tum): A layer.

Stratum basalis (ba-SAL-is): The layer of the endometrium next to the myometrium that is maintained during menstruation and gestation and produces a new stratum functionalis following menstruation or parturition.

Stratum functionalis (fank-shun-AL-is): The layer of the endodermium next to the uterine cavity that is shed during menstruation and that forms the maternal portion of the placenta during gestation.

Stretch receptor: Receptor in the walls of blood vessels, airways, or organs that monitors the amount of stretching. Also termed baroreceptor.

Stroma (STRO-ma): The tissue that forms the ground substance, foundation, or framework of an organ, as opposed to its functional parts (parenchyma).

Subarachnoid (sub-ar-rák-noyd): A space between the arachnoid mater and the pia mater that surrounds the brain and spinal cord and through which cerebrospinal fluid circulates.

Subcutaneous (sub-kü-TÁ-né-us): Beneath the skin. Also called hypodermic (hi-pö-DER-mik).

Subcutaneous layer: A continuous sheet of areolar connective tissue and adipose tissue between the dermis of the skin and the deep fascia of the muscles. Also called the hypodermis.

Subdural (sub-DOO-rál): A layer between the dura mater and the arachnoid mater of the brain and spinal cord that contains a small amount of fluid.

Sublingual (sub-LING-gwał): One of a pair of salivary glands situated in the floor of the mouth deep to the mucous membrane and to the side of the lingual frenulum, with a duct (Rivinus') that opens into the floor of the mouth.

Submandibular (sub-MAN-di-bu-lár): One of a pair of salivary glands found inferior to the base of the tongue to the mucous membrane in the posterior part of the floor of the mouth, posterior to the sublingual glands, with a duct (Wharton's) situated to the side of the lingual frenulum. Also called the submaxillary (sub-MAK-si-lár-ě) gland.

Submu cosa (sub-mó-KOS-a): A layer of connective tissue located deep to a mucous membrane, as in the gastrointestinal tract or the urinary bladder; the submucosa connects the mucosa to the muscularis layer.

Submucosal plexus: A network of autonomic nerve fibers located in the superficial part of the submucosal layer of the small intestine. Also called the plexus of Meissner (MEIS-nér).

Substrate: A molecule upon which an enzyme acts.

Subthalamicum (sub-thal-a-MUS): Part of the diencephalon inferior to the thalamus; the substantia nigra and red nucleus extend from the midbrain into the subthalampus.

Sudorificus (soor-a-dor-IF-er-us): An apocrine or eccrine exocrine gland in the dermis or subcutaneous layer.

Sulcus (SUL-kus): A groove or depression between parts, especially between the convolutions of the brain. Plural is sulci (SUL-si).

Superficial inguinal (IN-gwi-nál) ring: A triangular opening in the aponeurosis of the external oblique muscle that represents the termination of the inguinal canal.

Superior (soo-PRÉ-ér-ě-or): Toward the head or upper part of the body.

Superior vena cava (svě-na cā-va): A large vein that collects blood from parts of the body superior to the heart and returns it to the right atrium.

Surface anatomy: The study of the structures that can be identified from the outside of the body.

Surfactant: Complex mixture of phospholipids and lipoproteins, produced by type II alveolar (septal) cells in the lungs, that decreases surface tension.

Suspensory ligament (sus-SEN-so-re-LIG-mant): A fold of peritoneum extending laterally from the surface of the ovary to the pelvic wall.

Suture (SOO-shur): An immovable fibrous joint that joins skull bones.

Sympathetic (sim-THET-ik): One of the two subdivisions of the autonomic nervous system, having cell bodies of preganglionic neurons in the lateral gray columns of the thoracic segment and the first two or three lumbar segments of the spinal cord; primarily concerned with processes involving the expenditure of energy.

Sympathetic trunk ganglion: A cluster of cell bodies of sympathetic postganglionic neurons lateral to the vertebral column, close to the body of a vertebra. These ganglia extend inferiorly through the neck, thorax, and abdomen to the coccyx on both sides of the vertebral column and are connected to one another to form a chain on each side of the vertebral column. Also called sympa-thetic chain or vertebral chain ganglia.

Symphysis: Synthesis (SYN-fi-sis): A line of union. A slightly movable cartilaginous joint such as the pubic symphysis.

Symptom (SIMP-tum): A subjective change in body function not apparent to an observer, such as pain or nausea, that indicates the presence of a disease or disorder of the body.

Synapse (SIN-ap): The functional junction between two neurons or between a neuron and an effector, such as a muscle or gland; may be electrical or chemical.

Synapsis (SYN-ap-sis): The pairing of homologous chromosomes during prophase I of meiosis.

Synaptic (SYN-ap-tik): The narrow gap at a chemical synapse that separates the axon terminal of one neuron from another neuron or muscle fiber (cell) and across which a neurotransmitter diffuses to affect the postsynaptic cell.

Synaptic end bulb: Expanded distal end of an axon terminal that contains synaptic vesicles. Also called a synaptic knob.

Synaptic vesicle: Membrane-enclosed sac in a synaptic end bulb that stores neurotransmitters.

Synarthrosis (sin-ar-THRO-žis): An immovable joint such as a suture, gomphosis, or synchondrosis.

Synchronosis (sin-kron-DRO-sis): A cartilaginous joint in which the connecting material is hyaline cartilage.

Syndesmosis (sin-dez-MÖ-sis): A slightly movable joint in which articulating bones are united by fibrous connective tissue.

Synergist (SYN-e-rig-st): A muscle that assists the prime mover by reducing undesired action or unnecessary movement.

Synergistic (SYN-e-rig-TIK):Effect: A hormonal interaction in which the effects of two or more hormones
G26 GLOSSARY

acting together is greater or more extensive than the sum of each hormone acting alone.

Synostosis (sin’-os-TO-sis) A joint in which the dense fibrous connective tissue that unites bones at a suture has been replaced by bone, resulting in a complete fusion across the suture line.

Synovial (st-NO-vē-al) cavity The space between the articulating bones of a synovial joint, filled with synovial fluid. Also called a joint cavity.

Synovial fluid Secretion of synovial membranes that lubricates joints and nourishes articular cartilage.

Synovial joint A fully movable or diarthrotic joint in which a synovial (joint) cavity is present between the two articulating bones.

Synovial membrane The deeper of the two layers of the articular capsule of a synovial joint, composed of areolar connective tissue that secretes synovial fluid into the synovial (joint) cavity.

System An association of organs that have a common function.

Systemic (sis-TEM-ik) Affecting the whole body; generalized.

Systemic anatomy The anatomic study of particular systems of the body, such as the skeletal, muscular, nervous, cardiovascular, or urinary systems.

Systemic circulation The routes through which oxygenated blood flows from the left ventricle through the aorta to all the organs of the body and deoxygenated blood returns to the right atrium.

Systole (SIS-tō-lē) In the cardiac cycle, the phase of contraction of the heart muscle, especially of the ventricles.

Systolic (sis-TOL-ik) blood pressure The force exerted by blood on arterial walls during systolic contraction; the highest pressure measured in the large arteries, about 120 mmHg under normal conditions for a young adult.

T T cell A lymphocyte that becomes immunocompetent in the thymus and can differentiate into a helper T cell or a cytotoxic T cell, both of which function in cell-mediated immunity.

T wave The deflection wave of an electrocardiogram that represents ventricular repolarization.

Tachycardia (tak’-i-KAR-dē-a) An abnormally rapid resting heartbeat or pulse rate (over 100 beats per minute).

Tactile (TAK-tl) Pertaining to the sense of touch.

Tactile disc See Merkel disc.

Target cell A cell whose activity is affected by a particular hormone.

Tarsal bones The seven bones of the ankle. Also called tarsals.

Tarsal gland A sebaceous gland that opens on the edge of each eyelid. Also called a Meibomian gland.

Tarsal plate A thin, elongated sheet of connective tissue, one in each eyelid, giving the eyelid form and support. The aponeurosis of the levator palpebrae superioris is attached to the tarsal plate of the superior eyelid.

Tarsus (TAR-sus) A collective term for the seven bones of the ankle.

Tectorial (tek-TÖ-rē-al) membrane A gelatinous membrane projecting over and in contact with the hair cells of the spiral organ (organ of Corti) in the cochlear duct.

Teeth (TE-th) Accessory structures of digestion, composed of calcified connective tissue and embedded in bony sockets of the mandible and maxilla, that cut, chew, crush, and grind food. Also called dentes (DEN-tēz).

Telophase (TEL-ö-fāz) The final stage of mitosis.

Tendon (TEN-don) A white fibrous cord of dense regular connective tissue that attaches muscles to bone.

Tendon organ A proprioceptive receptor, sensitive to changes in muscle tension and force of contraction, found chiefly near the junctions of tendons and muscles. Also called a Golgi tendon organ.

Tendon reflex A polysynaptic, ipsilateral reflex that protects tendons and their associated muscles from damage that might be brought about by excessive tension. The receptors involved are called tendon organs (Golgi tendon organs).

Teniae coli (TE-nē-é KO-ē-lē) The three flat bands of thickened, longitudinal smooth muscle running the length of the large intestine, except in the rectum. Singular is tenia coli.

Tentorium cerebelli (ten-TO-rē-um ser’-ē-BEL-ē) A transverse shelf of dura mater that forms a partition between the occipital lobe of the cerebral hemispheres and the cerebellum and that covers the cerebellum.

Teratogen (TER-á-tō-jen) Any agent or factor that causes physical defects in a developing embryo.

Terminal ganglion (TER-min-al GAN-gle-ōn) A cluster of cell bodies of parasympathetic postganglionic neurons either lying very close to the visceral effectors or located within the walls of the visceral effectors supplied by the postganglionic neurons.

Testis (TES-tis) Male gonad that produces sperm and the hormones testosterone and inhibin. Also called a testicle.

Testosterone (tes-TOS-te-rōn) A male sex hormone secreted by interstitial endocrinocytes ( Leydig cells) of a mature testis; needed for development of sperm; together with a second androgen termed dihydrotestosterone (DHT), controls the growth and development of male reproductive organs, secondary sex characteristics, and body growth.

Testis (TES-tis) Male gonad that produces sperm and the hormones testosterone and inhibin. Also called a testicle.

Thyroid cartilage (THI-rōyd KAR-ti-lij) The largest single cartilage of the larynx, consisting of two fused plates that form the anterior wall of the larynx.

Thyroid follicle (FOL-i-kul) Spherical sac that forms the parenchyma of the thyroid gland and consists of follicular cells that produce thyroxine (T4) and triiodothyronine (T3).

Thyroid gland An endocrine gland with right and left lateral lobes on either side of the trachea connected by an isthmus; located anterior to the trachea just inferior to the cricoid cartilage; secretes thyroxine (T4), triiodothyronine (T3), and calcitonin.

Thyroid-stimulating hormone (TSH) A hormone secreted by the anterior pituitary that stimulates the synthesis and secretion of thyroxine (T4) and triiodothyronine (T3).

Thyroxine (thi-ROK-sīn) (T4) A hormone secreted by the thyroid gland that regulates metabolism, growth and development, and the activity of the nervous system.

Tic Spasmodic, involuntary twitching of muscles that are normally under voluntary control.

Tissue A group of similar cells and their intercellular substance joined together to perform a specific function.

Tissue rejection Phenomenon by which the body recognizes the protein (HLA antigens) in transplanted tissues or organs as foreign and produces antibodies against them.

Tongue A large skeletal muscle covered by a mucous membrane located on the floor of the oral cavity.

Tonsil (TON-sil) An aggregation of large lymphatic nodules embedded in the mucous membrane of the throat.

Toxic (TÖ-lik) A poison.

Toxic (TÖ-lik) A poison.

Topical (TOP-i-kal) Applied to the surface rather than ingested or injected.
Torn cartilage A tearing of an articular disc (meniscus) in the knee.

Tracheula (tra-BEK-ə-la) Irregular latticework of thin plates of spongy bone tissue. Fibrous cord of connective tissue serving as supporting fiber by forming a septum extending into an organ from its wall or capsule. Plural is tracheulae (tra-BEK-ə-lē).

Tracheae carinaeae (KAR-nē-ə) Ridges and folds of the myocardium in the ventricles.

Trachea (TRAK-eə) Tubular air passageway extending from the larynx to the fifth thoracic vertebra. Also called the windpipe.

Tract A bundle of nerve axons in the central nervous system.

Transplantation (TRANZ-plan-TA-ʃun) The transfer of living cells, tissues, or organs from a donor to a recipient or from one part of the body to another in order to restore a lost function.

Transverse colon (trans-VERS KO-lon) The portion of the large intestine extending across the abdomen from the right colic (hepatic) flexure to the left colic (splenic) flexure.

Transverse fissure (FISH-ə) The deep clef that separates the cerebrum from the cerebellum.

Transverse plane A plane that divides the body or organs into superior and inferior portions. Also called a cross-sectional or horizontal plane.

Transverse tubes (TOO-būs) (T tubules) Small, cylindrical invaginations of the sarcosome of striated muscle fibers (cells) that conduct muscle action potentials toward the center of the muscle fiber.

Tremor (TREM-ər) Rhythmic, involuntary, purposeless contraction of opposing muscle groups.

Triad (TRI-əd) A complex of three units in a muscular girdle, consisting of the arm, forearm, wrist, hand, and fingers. Also called upper extremity.

Tricuspid (trI-KUS-pid) Pertaining to an unnatural attachment of the umbilical cord to the fetus. Also called the navel.

Umbilical cord The long, ropelike structure containing the umbilical arteries and vein that connect the fetus to the placenta.

Umbilicus (um-bi-LI-kus or um-bi-LI-kus) A small scar on the abdomen that marks the former attachment of the umbilical cord to the fetus. Also called the navel.

Upper limb The appendage attached at the shoulder girdle, consisting of the arm, forearm, wrist, hand, and fingers. Also called upper extremity.

Urethra (uR-e-thra) The duct from the urinary bladder to the exterior of the body that conveys urine in females and urine and semen in males.

Urinalysis A chemical, physical, and microscopic examination of the blood, usually resulting from severe kidney malfunction.

Uterine (U-te-rin) Pertaining to an unnatural swelling, as in the case of a varicose vein.

Vagina (va-JI-na) A muscular, tubular organ that leads from the uterus to the vestibule, situated between the urinary bladder and the rectum of the female.

Vas A vessel or duct.

Varicocele (VAR-i-kō-sēl) A twisted vein; especially, the accumulation of blood in the veins of the spermatic cord.

Vasectomy (va-SEK-tō-mē) A means of sterilization of males in which a portion of each ductus
G28 GLOSSARY

(VAS) deferens is removed.
Vasconstriction (vā-z’-ō-kōn-STRIK-shun) A decrease in the size of the lumen of a blood vessel caused by contraction of the smooth muscle in the wall of the vessel.
Vasodilation (vā’ z’-ō-DI-lā-shun) An increase in the size of the lumen of a blood vessel caused by relaxation of the smooth muscle in the wall of the vessel.
Vein (VEY-n) A blood vessel that conveys blood from tissues back to the heart.
Vena cava (VE-n-ə kā-və) One of two large veins that open into the right atrium, returning to the heart all of the deoxygenated blood from the systemic circulation except from the coronary circulation.
Ventral (VEN-tral) Pertaining to the anterior or front side of the body; opposite of dorsal.
Ventral ramus (VER-tər-al) The anterior branch of a spinal nerve, containing sensory and motor fibers to the muscles and skin of the anterior surface of the head, neck, trunk, and the limbs.
Ventricle (VEN-tri-kul) A cavity in the brain filled with cerebrospinal fluid. An inferior chamber of the heart.
Ventricular fibrillation (VEN-trik-ər fib-ri-LÅ-shun) Asynchronous ventricular contractions; unless reversed by defibrillation, results in heart failure.
Venule (VEN-ū-lə) A small vein that collects blood from capillaries and delivers it to a vein.
Vermiform appendix (VER-mi-form a-PEH-niks) A twisted, coiled tube attached to the cecum.
Vermis (VER-mis) The central constricted area of the cerebellum that separates the two cerebellar hemispheres.
Vertebral (VER-te-bral) canal A cavity within the vertebral column formed by the vertebral foramina of all the vertebrae and containing the spinal cord. Also called the spinal canal.
Vertebral column The 26 vertebrae of an adult and 33 vertebrae of a child; encloses and protects the spinal cord and serves as a point of attachment for the ribs and back muscles. Also called the backbone, spine, or spinal column.
Vesicle (VES-i-kul) A small bladder or sac containing liquid.
Vescicouterine (ves’-ik-ō-Ü-ter-in) pouch A shallow pouch formed by the reflection of the peritoneum from the anterior surface of the uterus, at the junction of the cervix and the body, to the posterior surface of the urinary bladder.
Vestibular (ves-TIB-ə-lər) apparatus Collective term for the organs of equilibrium, which includes the saccule, utricle, and semicircular ducts.
Vestibular membrane The membrane that separates the cochlear duct from the scala vestibuli.
Vestibule (VES-ti-bū-lə) A small space or cavity at the beginning of a canal, especially the inner ear, larynx, mouth, nose, and vagina.
Villus (VIL-lus) A projection of the intestinal mucosal cells containing connective tissue, blood vessels, and a lymphatic vessel; functions in the absorption of the end products of digestion. Plural is villi (VIL-ı) (VIL-1).
Viscera (VIS-er-a) The organs inside the ventral body cavity. Singular is viscus (VIS-kus).
Visceral (VIS-er-al) Pertaining to the organs or to the covering of an organ.
Visceral effectors (vis-ER-ək-torz) Organs of the ventral body cavity that respond to neural stimulation, including cardiac muscle, smooth muscle, and glands.
Vitamin An organic molecule necessary in trace amounts that acts as a catalyst in normal metabolic processes in the body.
Vitreous (VES-trik-ər) body A soft, jellylike substance that fills the vitreous chamber of the eyeball, lying between the lens and the retina.
Vocal folds Pair of mucous membrane folds below the ventricular folds that function in voice production. Also called true vocal cords.
Volkman’s canal See Perforating canal.
Vulva (VUL-va) Collective designation for the external genitalia of the female. Also called the pudendum (poo-DEN-dum).

W
Wallerian (wal-LE-rē-an) degeneration Degeneration of the portion of the axon and myelin sheath of a neuron distal to the site of injury.
Wandering macrophage (MAK-ro-fāj) Phagocytic cell that develops from a monocyte, leaves the blood, and migrates to infected tissues.

White matter Aggregations or bundles of myelinated and unmyelinated axons located in the brain and spinal cord.

White pulp The regions of the spleen composed of lymphatic tissue, mostly B lymphocytes.

White ramus communicans (RAH-mus kō-MÜ-νi-kans) The portion of a preganglionic sympathetic axon that branches from the anterior ramus of a spinal nerve to enter the nearest sympathetic trunk ganglion.

X
Xiphoid (ZIF-foyd) Sword-shaped.
Xiphoid (ZIF-foyd) process The inferior portion of the sternum is the xiphoid process.

Y
Yolk sac An extraembryonic membrane composed of the exocoelomic membrane and hypoblast. It transfers nutrients to the embryo, is a source of blood cells, contains primordial germ cells that migrate into the gonads to form primitive germ cells, forms part of the gut, and helps prevent desiccation of the embryo.

Z
Zona fasciculata (ZÖ-na fa-SIK-ə-LA-ta) The middle zone of the adrenal cortex consisting of cells arranged in long, straight cords that secrete glucocorticoid hormones, mainly cortisol.
Zona glomerulosa (gro-mer-ə-LÖ-sa) The outer zone of the adrenal cortex, directly under the connective tissue covering, consisting of cells arranged in arched loops or round balls that secrete mineralocorticoid hormones, mainly aldosterone.
Zona pellucida (pe-LÖO-si-da) Clear glycoprotein layer between a secondary oocyte and the surrounding granulosa cells of the corona radiata.
Zona reticularis (ret-ik-ə-LAR-is) The inner zone of the adrenal cortex, consisting of cords of branching cells that secrete sex hormones, chiefly androgens.
Zygote (ZI-got) The single cell resulting from the union of male and female gametes; the fertilized ovum.

In the life sciences, an eponym is the name of a structure, drug, or disease that is based on the name of a person. For example, you may be more familiar with the Achilles tendon than you are with its more anatomically descriptive term, the calcaneal tendon. Because eponyms remain in frequent use, this listing correlates common eponyms with their anatomical terms.

COMBINING FORMS, WORD ROOTS, PREFIXES, AND SUFFIXES

Many of the terms used in anatomy and physiology are compound words; that is, they are made up of word roots and one or more prefixes or suffixes. For example, leukocyte is formed from the word roots leuko- meaning “white”, a connecting vowel (o), and -cyte meaning “cell.” Thus, a leukocyte is a white blood cell. The following list includes some of the most commonly used combining forms, word roots, prefixes, and suffixes used in the study of anatomy and physiology. Each entry includes a usage example. Learning the meanings of these fundamental word parts will help you remember terms that, at first glance, may seem long or complicated.

### PREFIXES

- A- | An- | without, lack of, deficient | Anesthesia |
- Ab- | Away from | Abnormal |
- Ad- | To, toward | Addiction |
- Al- | White | Albino |
- Alveol- | Cavity, socket | Alveolus |
- Andro- | Male, masculine | Androgen |
- Anti- | Against | Anticoagulant |
- Bas- | Base, foundation | Basal ganglia |
- Bi- | Two, double | Biceps |
- Brady- | Slow | Bradycardia |
- Cata- | Down, lower | Catabolism |
- Circum- | Around | Circumduction |
- Cirrh- | Yellow | Cirrhosis |
- Co-, Con-, | With, together | Congenital |
- Contra- | Against, opposite | Contraception |
- Crypt- | Hidden, concealed | Cryptorchidism |
- Cyano- | Blue | Cyanosis |
- De- | Down, from | Deciduous |
- Demi-, | Semi- | Hemiplegia |
- Di-, Diplo- | Two, double | Diploid |
- Dis- | Separation, apart | Dissection |
- Dys- | Painful, difficult | Dyspnea |
- E-, Ec-, Ef- | Out from, out of | Efferent neuron |
- Ecto-, Exo- | Outside | Ectopic pregnancy |
- Em-, En- | In | Emmetropia |
- Endo-, Endo- | Within, inside | Endocardium |
- Epil- | Upon, on | Epidermis |
- Eu- | Good, easy, normal | Eupnea |
- Ex-, Exo- | Outside, beyond | Exocrine gland |
- Extra- | Outside, beyond | Extracellular fluid |
- Fore- | Before, in front of | Forehead |
- Gen- | Origin | Genitalia |
- Gingiv- | Gum | Gingivitis |
- Hemi- | Half | Hemiplegia |
- Hetero-, Hetero- | Other, different | Heterozygous |
- Homeo-, Homo- | Unchanging, the same | Homeostasis |
- Hyper- | Above, excessive | Hyperglycemia |
- Hypo- | Under, beneath, deficient | Hypothalamus |
- In-, Im- | Inside, not | Incontinent |
- Infra- | Beneath | Infraorbital |
- Intera- | Among, between | Intercostal |
- Intra- | Within, inside | Intracellular fluid |
- Iso- | Equal, like | Isotonic |
- Juxta- | Near to | Juxtaglomerular apparatus |
- Latero- | Side | Lateral |
- Macro- | Large, great | Macrophage |
- Mal- | Bad, abnormal | Malnutrition |
- Medi-, Medio- | Middle | Medial |
- Mega-, Megalo- | Great, large | Megakaryocyte |
- Melan- | Black, Melanin | | |
- Meta- | After, beyond | Metacarpus |
- Micro- | Small | Microfilament |
- Mono- | One | Monounsaturated fat |
- Neo- | New | Neonatal |
**Suffixes**

-able capable of, having ability to: Viable.
-ae, -al pertaining to: Cardiac.
-algia painful condition: Myalgia.
-an, -ian pertaining to: Circadian.
-ant having the characteristic of: Malignant.
-ary connected with: Ciliary.
-asis, -asia, -esis, -osis condition or state of: Hemostasis.
-asthenia weakness: Myasthenia.
-ation process, action, condition: Inhalation.
-centesis puncture, usually for drainage: Amniocentesis.
-cid, -cide, -cis, cut, kill destroy: Spermicide.
-ectomy, -ectomy excision of, removal of: Thyroidectomy.
-emia condition of blood: Anemia.
-esthesia sensation, feeling: Anesthesia.
-fer carry: Effervescent.
-gen agent that produces or originates: Pathogen.
-genic producing: Pyogenic.
-gram record: Electrocardiogram.
-graph instrument for recording: Electroencephalograph.
-ia state, condition: Hypermetropia.
-ician person associated with: Pediatrician.
-ics art of, science of: Optics.
-ism condition, state: Rheumatism.
-itis inflammation: Neuritis.
-logy the study or science of: Physiology.
-lysis dissolution, loosening, destruction: Hemolysis.
-malacia softening: Osteomalacia.
-megaly enlarged: Cardiomegaly.
-mers, -mers parts: Polymers.
-ma tumor: Fibroma.
-osis condition, disease: Necrosis.
-ostomy create an opening: Colostomy.
-otomy surgical incision: Tracheostomy.
-pathy disease: Myopathy.
-penia deficiency: Thrombocytopenia.
-phile, -phobia fear of, aversion to: Hydrophilic.
-phobe, -phobia: Fear of, aversion to: Photophobia.
-plasia, -plasty forming, molding: Rhinoplasty.
-pnea breath: Apnea.
-poiesis making: Hemopoiesis.
-ptosis falling, sagging: Blepharoptosis.
-rrhage bursting forth, abnormal discharge: Hemorrhage.
-rrhea flow, discharge: Diarrhea.
-scope instrument for viewing: Bronchoscope.
-stomy creation of a mouth or artificial opening: Tracheostomy.
-tomy cutting into, incision into: Laparotomy.
-tripsy crushing: Lithotripsy.
-trophy relating to nutrition or growth: Atrophy.
-uria urine: Polyuria.
